ACKNOWLEDGEMENTS

Firstly, I would like to acknowledge my deep gratitude to Prof. Seung-Koo Lee, who has been training me in neuroradiology division, for the continuous support of my Ph.D. study and related research.

Besides my advisor, I would like thank the rest of my thesis committee : Prof. Se Hoon Kim, Prof. Hyun Seok Choi, Prof. Seok-Gu Kang, and Prof. Jong Hee Chang, for their insightful comments and encouragement.

Special thanks to Prof. Sung Soo Ahn, who has provided help for study design and financial support.

ABSTRACT

Value of Amide Proton Transfer Imaging in Correlation with Histopathological Grades of Adult Diffuse Gliomas : Comparison and Incremental Value with Dynamic Susceptibility Contrast-Enhanced MRI and Diffusion Weighted Imaging

Yoon Seong Choi

(Directed by Professor Seung-Koo Lee)

Purpose: Amide proton transfer (APT), a subtype of chemical exchange saturation transfer, is a novel technique to detect concentration of endogenous peptide or protein without exogenous contrast agent administration. We investigated the difference in APT values according to histopathological grades, and compared the diagnostic value of APT with relative cerebral blood volume (rCBV) from dynamic susceptibility contrast-enhanced (DSC) MRI and apparent diffusion coefficient (ADC) from diffusion weighted imaging (DWI) for histopathological grades in adult diffuse gliomas. We also investigated the incremental value of APT over ADC and rCBV for discriminating high grade and low grade gliomas.

Material and Methods: The study cohort consisted of 39 adult patients with histopathologically proven diffuse glioma who underwent preoperative APT imaging, with 34 patients available for preoperative DSC MRI and DWI. Regions of interest were obtained from circles manually placed at the area with high signal in APT and rCBV map, and

low signal in ADC map. APT signal was compared according to WHO grade or low vs high grade of glioma. Diagnostic ability to discriminate high grade glioma from low grade glioma were compared between APT, ADC, and rCBV by using Receiver operative characteristic (ROC) analysis, and incremental diagnostic value of APT over ADC and rCBV were assessed by using integrated discrimination index. Also, the correlation between APT values and Ki-67 labeling index (LI) was assessed by linear regression.

Results: The APT SI values were $0.82 \pm 0.36\%$ in grade II gliomas, $1.73 \pm 0.86\%$ in grade III, and $2.62 \pm 0.78\%$ in grade IV gliomas, which showed significant difference between grade II and III ($p=0.018$), III and IV ($p = 0.010$), as well as II and IV ($p < 0.001$). The diagnostic value to discriminate between high and low grade glioma was not significantly different between APT, ADC and rCBV, with area under the ROC curve (AUC) of 0.890, 0.917, and 0.947, respectively. ($p > 0.05$ for each comparison) Incremental diagnostic value of APT was significant over ADC ($p = 0.003$), and not significant over rCBV ($p=0.066$). APT signals were significantly correlated with Ki-67 LI. ($p=0.001$, $R^2 = 0.26$)

Conclusion: APT imaging can be useful, and have incremental value over ADC for predicting the histopathological grades of adult diffuse gliomas. APT SI can be correlated with Ki-67 LI.

Key words : Glioma, Grade, Magnetic resonance imaging, amide proton transfer, chemical exchange saturation transfer

I. INTRODUCTION

Glioma is the most common brain tumor and glioblastoma is the most malignant brain tumor in adults.^{1,2} Discrimination between high and low grade glioma is of clinical relevance, because prognosis and treatment strategies are substantially different according to glioma grades.³ Surgical resection followed by concurrent chemoradiation with temozolomide is standard treatment for high grade glioma,³ and undergrading of high grade glioma as low grade glioma can lead to insufficient and less aggressive treatment.

The gold standard for glioma grades and molecular or genetic profiles is surgical sampling which takes invasive procedure and risk of sampling from suboptimal site and undergrading of tumor, considering intratumoral heterogeneity of high grade gliomas. Thus, advanced MR techniques such as dynamic susceptibility contrast-enhanced (DSC) MRI and diffusion weighted imaging (DWI) have been utilized as noninvasive imaging biomarker. Many previous studies investigated the relative cerebral blood volume (rCBV) from DSC MRI and apparent diffusion coefficient (ADC) from DWI in correlation with glioma grade, genetic profile or prognosis, however with some conflicting results.⁴⁻¹¹

Amide proton transfer (APT) imaging is a subtype of chemical exchange

saturation transfer (CEST) imaging that reflects concentration of endogenous peptides or proteins without contrast agent administration.¹²⁻¹⁴ In APT imaging, a pulse with radiofrequency of amide (-NH) proton (3.5ppm) in peptides and proteins selectively saturates the signal from amide protons and these saturated amide protons exchange with protons from bulk water, consequently reducing the signal at 3.5ppm from bulk water. Thus, peptides and protein concentration can be indirectly assessed from calculating the asymmetric signal decrease from bulk water at 3.5ppm, although other factors such as pH or temperature can also affect the APT signal intensity (SI).¹²⁻¹⁶ Several previous studies investigated APT imaging in brain tumor. Previous studies reported that APT SI in brain tumor was mainly attributed to protein concentration,¹⁷ and APT SI was higher in brain tumor than normal tissue.¹⁸ Togao et al.¹⁹ obtained APT images from one dominant section of gliomas and reported that APT imaging can be useful for predicting histopathological grade of glioma. However, protocol of APT imaging needs to be optimized and validated in clinical setting and given that other advanced MR techniques such as DSC MRI or DWI is available in clinical setting, compatibility and incremental value of APT with ADC or rCBV for predicting glioma grades are of clinical importance, which has not been elucidated.

The purpose of this study was to investigate the diagnostic value of APT compared with those of ADC and rCBV, and incremental diagnostic value of APT over ADC and rCBV for predicting histopathological grade in diffuse gliomas in adults, with clinically optimized APT imaging protocols. We also investigated the correlation between APT SI and Ki-67 labeling index (LI).

II. MATERIALS AND METHODS

1. Protocol optimization with phantom experiment

Considering that protein concentration, pH, and radiofrequency (RF) saturation power and duration, RF saturation power was pivotal for APT imaging

protocol optimization, which was optimized to visualize the signal difference according to various protein concentrations so that the signal differences between brain tumor and normal tissue are well visualized. Phantom experiment for protocol optimization was performed with two sequences : three dimensional fast field echo (3D FFE) and three dimensional gradient and spine echo (3D GRASE) as described elsewhere.²⁰⁻²³ The first experiment was conducted with 3D FFE and 4 phantoms with 0% and 5% bovine serum albumin (BSA) at pH 6.5 and 7.4, respectively. Each phantom was scanned with varied RF powers of 0.5 μ T, 1 2 μ T, and 3 μ T with RF durations of 35msec, 70msec and 105 msec, thus 4 phantoms x 4 RF powers x 3 RF durations = 48 times of APT imaging were performed. In the second experiment, a phantom with more variable BSA concentration and pH, consisting of 2%, 4%, 8% and 16% BSA at pH 7.4, and pH 6, 6.5, 7, and pH 7.4 a 16% BSA, as shown in Figure 1, was scanned with both 3D FFE and GRASE sequences with RF powers of 1 μ T, 2 μ T, 3 μ T and 4 μ T and fixed RF durations of 35msec for FFE and 200ms for GRASE sequence.

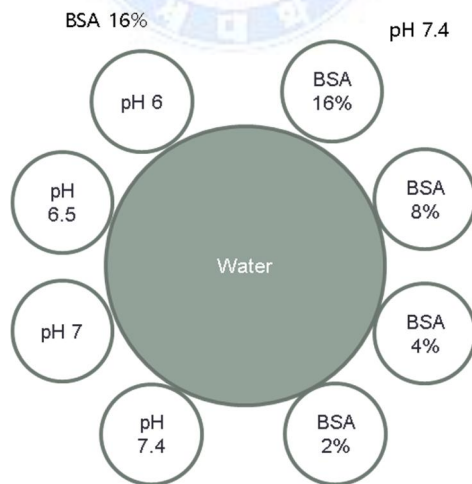

Fig. 1. A phantom with variable BSA concentrations and pH for protocol optimization

2. Patients

The cohort of this study consisted of thirty-nine consecutive adult patients with histopathologically proven diffuse glioma who underwent preoperative MRI including APT imaging from Nov, 2014 to June, 2015, with thirty-four patients among them available for preoperative DWI and DSC MRI. The mean age of cohort was 47.2 ± 16.8 years old and male to female ratio was 21:18. The interval from APT imaging, DWI and DSC MRI to operation was 1.2 ± 0.4 days.

3. Image acquisition

MRI studies were performed using a 3T system (Achieva, Philips Healthcare, Netherland, Best) and 32 channel receive head coil with transmit body coil. APT-weighted imaging was acquired using three-dimensional (3D) gradient-and spin-echo (GRASE) approach,²³ with the following parameters : voxel size, 2.2×2.2 mm; slice thickness, 4.4 mm; repetition time/echo time, 3000 msec/17 msec; TSE factor, 22; EPI factor, 7; and number of slices, 15 to cover entire tumor volume. By 4 repetitions at ± 3.5 ppm with six saturation frequency offsets (± 3.0 , ± 3.5 and ± 4.0 ppm), sufficient signal-to-noise ratio(SNR) could be achieved within clinical time frame. APT imaging was conducted with RF saturation amplitude of $2 \mu\text{T}$ and total duration of 800ms consisting of four block pulsed saturation scheme. Water frequency shift due to field inhomogeneity was measured in a separate scan using the water saturation shift referencing method²⁴ with 21 offset frequencies ranging from -1.25 ppm to 1.25 ppm at a step of 0.125 ppm (16 Hz) with one reference scan without saturation RF pulse resulting in full Z-spectrum within the offset range. This scan was acquired with repetition time/echo time of 1250 msec/17 msec and RF saturation amplitude of $0.5 \mu\text{T}$ with total duration of 400 ms consisting two block pulsed saturation scheme and the same imaging parameters as used in APT imaging. Both the APT and water saturation shift referencing scans were performed prior to contrast-enhanced T1-weighted scan. Total acquisition time

was 7 min 36 sec for both water saturation shift referencing and APT scans.

Other conventional MR imaging sequences included T2-weighted turbo spin-echo imaging, FLAIR turbo spin-echo imaging, and contrast-enhanced T1-weighted gradient-echo imaging. Transverse T2-weighted turbo spin-echo images were obtained with the following parameters: repetition time /echo time, 4629 msec/80 msec; number of slices, 90; voxel size, 0.98 x 1.02; slice thickness, 2.0 mm; scan time, 4 minutes 19 seconds. Transverse fluid attenuated inversion recovery (FLAIR) turbo spin-echo images were obtained with the following parameters: repetition time /echo time /inversion time, 11000 msec/125 msec/2800 msec; number of slices, 100; voxel size, 0.98 x 1.05; slice thickness, 2.0 mm, scan time, 8 minutes 48 seconds. Transverse gadolinium-enhanced T1-weighted gradient-echo images were acquired with the following parameters: repetition time/echo time, 2000 msec/1000 msec; number of slices, 90; voxel size, 0.98 x 0.79; slice thickness, 2.0 mm; scan time, 13 minutes 12 seconds.

4. Image postprocessing analysis.

After water frequency shift correction, magnetization transfer ratio asymmetry (MTR_{asym}) values at ± 3.5 ppm with respect to the water frequency, so called APT-weighted SI values were calculated^{15,16} :

$$\text{MTR}_{\text{asym}}(+3.5\text{ppm}) = \frac{S_{\text{sat}}(-3.5\text{ppm}) - S_{\text{sat}}(+3.5\text{ppm})}{S_0}$$

where S_0 and $S_{\text{sat}}(\Delta\omega)$ are MRI signal without and with saturation RF pulse at offset frequency of $\Delta\omega$ at downfield ($+\Delta\omega$) and upfield ($-\Delta\omega$) from water center frequency. All postprocessing of APT images was performed with Matlab (MathWorks, Natick, MA). The full the water saturation shift referencing Z-spectrum was then fitted to a 12th order polynomial at each voxel, and the lowest signal in the fit after interpolation at higher spectral resolution (1Hz) was assumed to be an actual water resonance frequency resulting in a water

center frequency offset at a corresponding voxel. The acquired APT data were organized according to the offsets, and the saturation images with the same offsets were averaged. The data for offsets (+4, +3.5, +3 ppm) and (-3, -3.5, -4 ppm) for each voxel were interpolated to 385 points over a frequency offset range from +5 to+2 ppm and -2 to -5 ppm, respectively, and shifted using the fitted water saturation shift referencing central frequency offset at the same voxel. Based on the shift-corrected data, the parameter map of APT SI was calculated using an MTR asymmetry at ± 3.5 ppm.

Single or multiple circular regions of interest (ROIs) were placed manually on the areas with high SI on APT and rCBV maps, and areas with low SI on ADC map, that corresponds to solid enhancing portion on T1-weighted images, in case of presence of enhancement, or non-enhancing solid portion avoiding cystic or necrotic portion on T2-weighted images in case of non-enhancing tumors. The mean values from the ROIs on APT, ADC, and rCBV maps were analyzed in statistical analysis, and rCBV values were normalized to the SI of contralateral normal appearing white matter. The size of an ROI at each lesion ranged from 180.5 mm² to 492.8 mm².

5. Pathological evaluation

The pathological diagnosis with glioma grade, and Ki-67 labelling index (LI) were determined from specimen of surgical sampling. WHO grades of gliomas were determined histopathologically by an experienced neuropathologist. The Ki-67 LI was determined based on the fields with the highest number of Ki-67-labeled cells through a generalized survey, and the percentage of positive cells was counted among approximately 1000 tumor cells.

6. Statistical analysis

Statistical analyses were performed with using R for Windows version 3.0.2 (R Foundation for Statistical Computing, Nashville, TN, USA). For 39

patients from the entire cohort, APT SI was compared according to WHO grade (II, III or IV) by using one-way analysis of variance (ANOVA) and post hoc comparison with Bonferroni correction. For 34 patients who underwent preoperative DWI and DSC MRI, APT SI, ADC and rCBV values were compared between low (WHO grade II) and high grade (WHO grade III or IV) of glioma, using Student t-test according to result of Shapiro-Wilk test for normal distribution. Diagnostic ability of APT, ADC and rCBV values to discriminate high grade glioma from low grade glioma were assessed and compared by using Receiver operative characteristic (ROC) analysis and the method by DeLong.²⁵ Robustness of ROC analysis was confirmed by bootstrapping with 1000 replication and bias-corrected 95% confidential interval for area under the ROC curve (AUC). Incremental diagnostic value of APT over ADC and rCBV were assessed by calculating integrated discrimination improvement (IDI) index described by Pencina et al.²⁶ as follows : integrated discrimination improvement = $(IS_{\text{new}} - IS_{\text{old}}) - (IP_{\text{new}} - IP_{\text{old}})$, where “new” refers to a model containing a new diagnostic tool of interest as APT in our study, in addition to conventional risk predictors, “old” pertains to the model containing only the conventional predictors as ADC and rCBV in our study, and IS and IP are the integrals of sensitivity and $(1 - \text{specificity})$, respectively. For 39 patients from the entire cohort, the correlation between APT values and Ki-67 LI was assessed using simple linear regression. P value <0.05 was considered statistically significant.

III. RESULTS

1. Protocol optimization with phantom experiments

Figure 2 shows result of the first phantom experiment conducted with 4 phantoms each with 0% and 4% BSA at pH 7.4 and pH 6.5. APT SI of 4% BSA phantom increased along with increased RF power and duration, regardless of pH, whereas APT SI of 0% BSA phantom did not change according to RF power, implicating that APT SI is attributed to protein concentration. No significant difference was found in APT SI according to pH change.

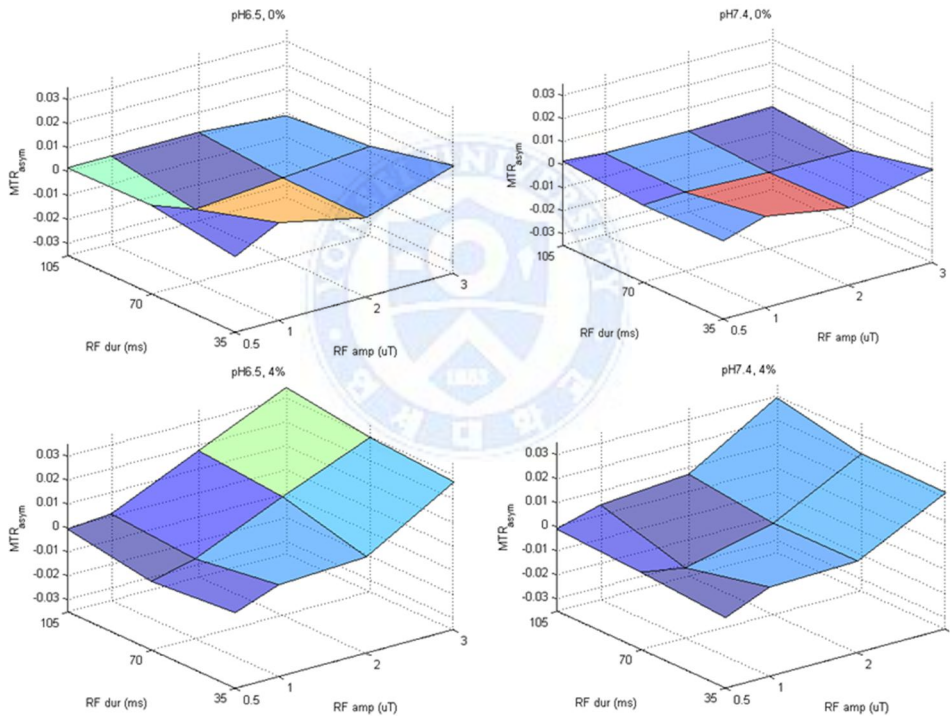

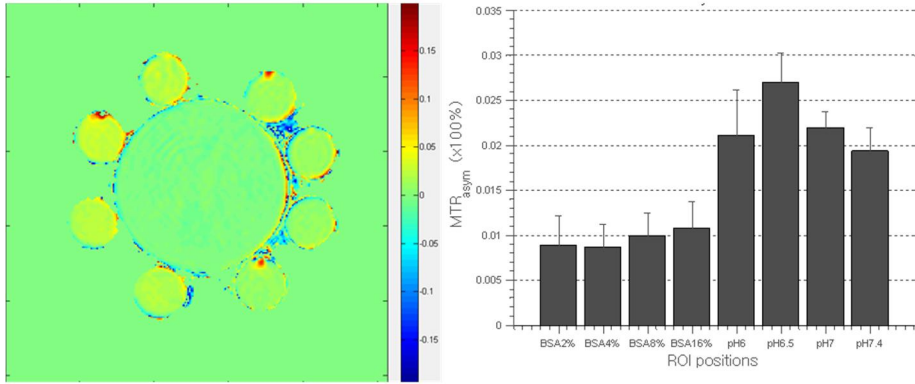

Fig. 2. Results of experiments with phantoms with 0% and 4% BSA at pH 7.4 and pH 6.5, and varied RF powers (0.5, 1, 2, and 3 μ T) and RF durations (35, 70, and 105msec).

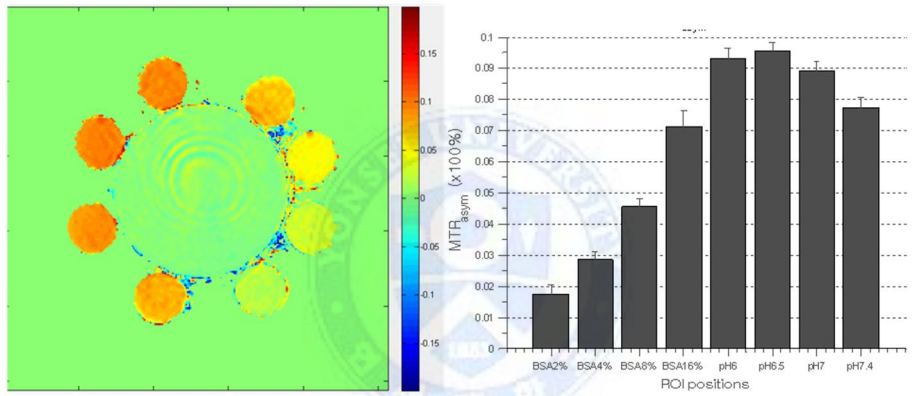

Figure 3 shows the result of the second experiment conducted with 3D FFE and GRASE, and a phantom with 2%, 4%, 8%, 16% BSA at pH 7.4 and pH 6, pH 6.5, pH 7, pH 7.4 at 16% BSA, as shown in Figure 1. In experiment with 3D GRASE sequence, APT SI obtained with 1 μ T RF power did not show the difference in BSA concentration, whereas APT SI obtained with 2 μ T, 3 μ T and 4 μ T RF power increased along with increased BSA concentration. In experiment with 3D FFE sequence, APT SI obtained with 1 μ T and 2 μ T RF power were not correlated with BSA concentration, and APT SI with 1 μ T RF power showed unexpected negative values. APT SI obtained with 3 μ T and 4 μ T RF power increased along with increased BSA concentration. Considering clinical feasibility and other previous reports, 3D GRASE sequence with RF power of 2 μ T, the minimum RF power with which APT SI was correlated with BSA concentration, and with RF duration of 200msec was chosen for patient scan in clinical setting.

2. Patients

Patient histologic and genetic characteristics are summarized in Table 1. The 39 patients consisted of 12 patients with grade II, 9 patients with grade III, and 18 patients with grade IV gliomas. 34 out of 39 patients underwent preoperative DWI and DSC MRI in addition to APT imaging.

Table 1. Histologic and molecular characteristics of the study cohort (n=39)

Histology	Number	Ki-67 LI
Grade II (n=12)		3.6 ± 2.2
Astrocytoma	5	
Oligodendroglioma	2	
Oligoastrocytoma	5	
Grade III (n=9)		11.9 ± 9.1
Anaplastic astrocytoma	2	
Anaplastic oligodendroglioma	1	
Anaplastic oligoastrocytoma	6	
Grade IV (n=18)		29.3 ± 29.5

Gliosarcoma	2	

3. Difference of APT SI according to glioma grades

Difference of APT SI according to glioma grades are summarized in Table 2 and shown in Figure 3 . The APT SI values were higher in higher glioma grade, which were 0.82 ± 0.36 % in grade II gliomas, 1.73 ± 0.86 % in grade III, and 2.62 ± 0.78 % in grade IV gliomas, showing significant difference between grade II and III ($p = 0.018$), III and IV ($p = 0.010$), as well as II and IV ($p < 0.001$).

Table 2. Differences in APT SI according to WHO grades. (n=39).

	APT SI	P value ^a
II	0.82 ± 0.37	-
III	1.73 ± 0.86	-
IV	2.63 ± 0.78	-
II vs III	-	0.018
II vs IV	-	<0.001
III vs IV	-	0.010

^a posthoc pairwise comparison with bonferroni correction after ANOVA

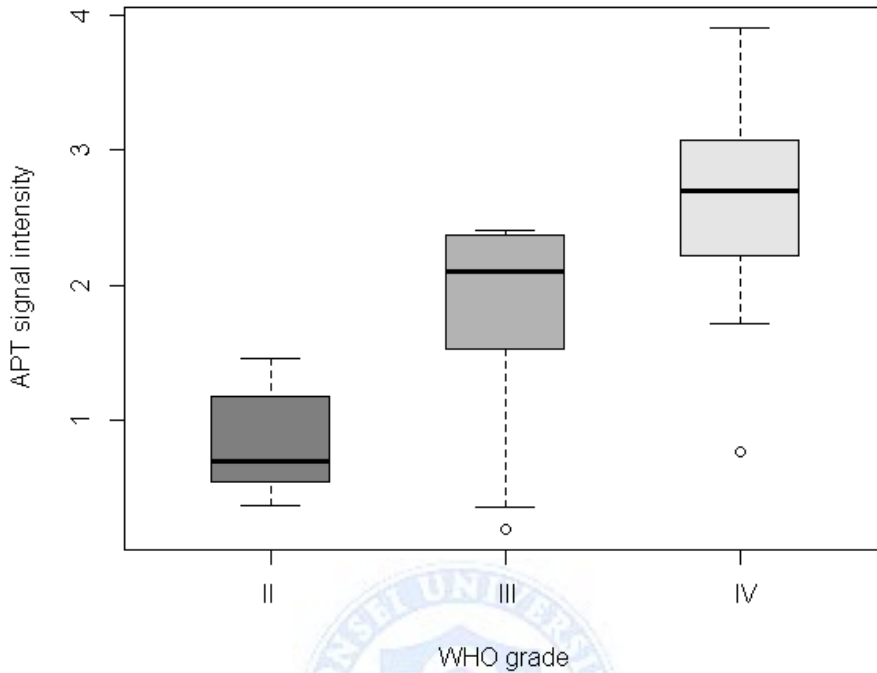

Fig. 4. Difference of APT signal intensity according to glioma grades.

4. Comparison of diagnostic value between APT, ADC and rCBV for glioma grading

Difference of APT, ADC, and rCBV values between low and high grade gliomas are summarized in Table 3 and depicted in Figure 4. APT and rCBV values were higher and ADC values were lower in high grade glioma than in low grade glioma with statistical significance. ($p < 0.001$ for all)

Results from ROC analysis for discriminating high grade from low grade glioma is summarized in Table 4 and depicted in Figure 5. In ROC analysis, APT, ADC and rCBV values showed excellent diagnostic performance with AUC of 0.890, 0.917, and 0.947, respectively. Although AUC of APT was lower than those of ADC and rCBV, no statistical significance was found among the diagnostic value of APT, ADC and rCBV, implicating compatibility of APT as a diagnostic tool for glioma grades. Representative images of APT SI,

ADC, and rCBV parameter maps from low and high grade gliomas are depicted in figure 6 and 7.

5. Incremental diagnostic value of APT over ADC and rCBV for glioma grading

Incremental diagnostic value of APT over ADC and rCBV for glioma grading assessed by IDI are summarized in Table 5. Combination of APT and ADC values showed better diagnostic performance than ADC alone for glioma grading, with increased AUC from 0.917 to 0.955 and statistical significance. ($p = 0.003$) (Figure 8) In contrast to combination of APT and ADC, combination of APT and rCBV did not achieve significance improvement in glioma grading ($p = 0.066$), though accuracy was increased from 85.3% to 91.2%.

Table 5. Incremental diagnostic values of APT SI over ADC and rCBV to discriminate high- and low-grade gliomas. (n=34)

		AUC (95%CI)	Sensitivity	Specificity	Accuracy	IDI
Over ADC	ADC	0.917(0.791-0.977)	86.4%	75.0%	82.4%	0.177
	ADC + APT	0.955(0.842-1.000)	90.9%	91.7%	91.2%	(P = 0.003)
Over rCBV	rCBV	0.947(0.798-1.000)	81.8%	91.7%	85.3%	0.096
	rCBV + APT	0.947(0.833-0.993)	90.9%	91.7%	91.2%	(P = 0.066)

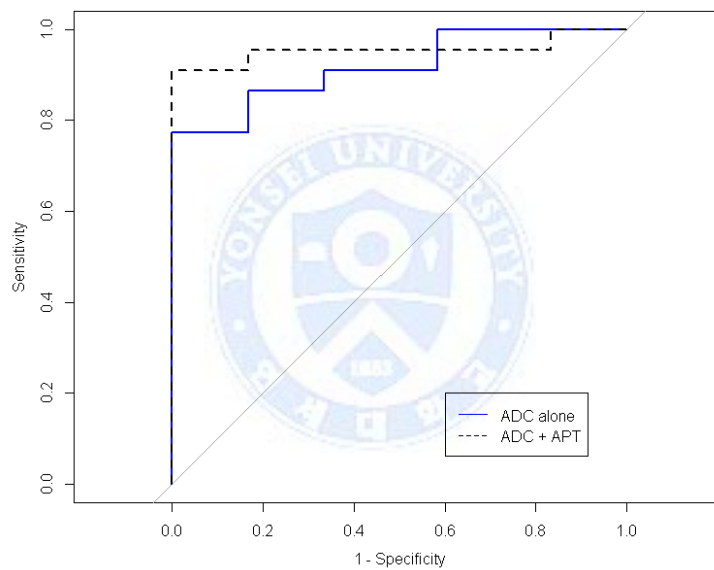

Fig. 9. ROC curves of ADC alone and APT + ADC for discriminating high grade from low grade gliomas.

6. Correlation between APT SI and Ki-67 LI

Figure 9 shows correlation between APT SI and Ki-67 LI. High grade gliomas had significantly higher Ki-LI than low grade gliomas (3.6 ± 2.2 vs 23.5 ± 25.7 , $p = 0.012$). In linear regression, APT SI showed significant positive correlation with Ki-67 LI. ($p=0.001$, $R^2 = 0.26$)

Fig. 10. Scatterplot of APT SI and Ki-67 LI.

IV. DISCUSSION

We investigated the correlation between APT SI and glioma grades, compared the diagnostic value of APT with ADC and rCBV, and incremental value of APT over ADC and rCBV for discriminating between high and low grade gliomas with optimized APT imaging protocol. APT showed diagnostic value compatible with ADC and rCBV and had incremental value over ADC and rCBV for glioma grading, with higher APT SI in high grade than low grade gliomas. Also, we found positive correlation between APT SI and Ki-67 LI.

Advanced MRI techniques such as DWI or DSC MRI have been recently utilized as noninvasive biomarkers that correlated with histopathological grades and molecular or genetic profiles of glioma.^{4-7,27} APT imaging, a subtype of CEST, can indirectly provide information about peptide or protein concentration within the tissue and has been investigated as an imaging biomarker in previous studies.¹²⁻¹⁶ Wen et al.¹⁸ analyzed 12 patients with high grade glioma, found that the average APT SI of the viable tumor cores and cystic cavities were significantly higher than those of peritumoral edema and

normal appearing white matter, and suggested that APT imaging at the protein and peptide level may enhance noninvasive identification of tissue heterogeneity in high grade brain tumors. Zhou et al.¹⁵ analyzed 6 rats with glioblastomas and radiation and suggested that viable glioma seen as hyperintense and radiation necrosis seen as hypointense to isointense could be clearly differentiated using APT MRI. Sagiya et al.²⁸ analyzed 9 mice with glioblastomas treated with temozolomide, found that the temozolomide-resistant recurrent tumor showed higher APT SI than temozolomide-sensitive tumor before treatment and suggested the potential of APT imaging as a biomarker for early detection of treatment response in mouse using 7T MRI. Togao et al.¹⁹ analyzed 37 human gliomas and found that the APT SI positively correlated with glioma grade, Ki-67 LI, and cell density with statistical significance. However, these previous studies have limited clinical feasibility, since APT imaging protocol was not optimized for clinical use, mouse models instead of human were scanned using experimental MRI with 4.7T or higher magnetic field, and human patients were scanned in only one representative slice of tumor. Herein, we optimized the APT imaging protocol using 3T MRI in clinic and validated APT imaging clinically in glioma patients.

In the phantom experiments for protocol optimization, APT SI values were higher in phantoms with higher BSA concentration and higher RF power and duration, whereas no significant difference was found in APT SI according to pH change. Since various factors including pH and asymmetric magnetization transfer from macromolecules, as well as protein concentration, can affect the APT SI, interpretation of APT SI of tumor is complicated. Lower APT SI values at 3.5ppm are theoretically expected in lower pH as proton exchange rate between amide and bulk water is slowed in lower pH, which is contrary to our results. However, previous studies that investigated the influence of pH on APT SI has found conflicting results. McVicar et al.²⁹ reported that APT SI decreased with decreasing pH, whereas Jones et al.³⁰ reported that APT SI obtained from

3.3~3.7ppm showed fluctuated and various value with pH change. Interpretation of results from these previous and our studies needs caution due to heterogeneous sequence and RF power and duration of APT imaging protocol. Although signal from APT-weighted images mainly depended on protein concentration, not on pH, when using 3T MRI in clinic and GRASE sequence with RF frequency of 2 μ T or above in our phantom experiments, underlying mechanism and exact contributors to APT SI still remains unclear.

ADC is considered as an index of cellularity and reflects tumor burden. Previous studies investigated the correlation of ADC with grade, molecular or genetic subclassification, or prognosis of glioma, but with conflicting results.^{4,8,9,27,31} rCBV reflects perfusion in tumor microenvironment, and high rCBV values have been known to be associated with high grade glioma and prognosis.^{5,7} While ADC does not require normalization to contralateral normal appearing white matter (NAWM), the voxel values on rCBV map reflects relative but not absolute cerebral blood volume, as implicated its name, so that rCBV requires normalization to contralateral normal appearing white matter in postprocessing. Prah et al.³² found that interobserver reliability of rCBV depends on the normalization or standardization methods, and within-subject coefficient of variation range 24%-67% for rCBV that is normalized to contralateral NAWM as in our study. In this study, rCBV showed the highest performance of glioma grading among APT, ADC and rCBV, and rCBV in combination with APT did not show significant improvement in diagnostic value compared to rCBV alone, in contrast to ADC with which APT imaging has incremental diagnostic value for glioma grading. These results should be interpreted cautiously considering variability of rCBV. It is possible that APT can have significant incremental value over rCBV depending on normalization, considering that reclassification by APT over rCBV was of borderline significance ($p=0.066$), although only 95% CI but not AUC changed in our results. The opposite is also possible for ADC, considering interobserver variability of ADC that depends on ROI selection.

Although no normalization is required for ADC postprocessing, Ahn et al.³³ found that interobserver variability of ADC changed according to ROI selection, and selection of multiple hot spot ROIs as in our study showed higher interobserver variability than selection of entire tumor for ROIs. Thus, further investigations using rCBV standardization and ROI selection with high interobserver reliability are necessary.

There were several limitations in our study, aside from retrospective manner. First, only small number of patients (n=39) were enrolled and 3 among them were unavailable for preoperative DWI and DSC MRI. Second, locus-specific correlations of APT SI to WHO grades and Ki-67 LI were not conducted. Glioma grade and Ki-67 LI may be heterogeneous considering previously reported intratumoral heterogeneity, especially in high grade glioma, and the ROIs on APT-weighted images may have different glioma grades and Ki-67 LI from those in the pathological report. Third, hot spot method placing several circular ROIs on the high APT and rCBV, and low ADC values were used instead of segmenting the entire enhancing tumor. Although Ahn et al.³³ suggested that hot spot method has higher interobserver variability than segmenting the entire tumor, Sakata et al.³⁴ reported that no significant difference in glioma grading ability was found among variable ROI selections on APT images, including placing ROIs on a single representative slice and all slices of whole tumor, and with and without normalization to contralateral NAWM. We used several circular ROIs without normalization for APT SI based on the previous study by Sakata et al., and used the same ROI selection for ADC and rCBV to compare the diagnostic value for discriminating high grade from low grade gliomas. In our opinion, although a ROI selection with higher interobserver reliability, such as semiautomatic segmentation of the entire enhancing tumor, have been better for more accurate comparison between APT, ADC, and rCBV, the resolution of APT imaging needs to be improved for fair coregistration with postcontrast T1-weighted images.

V. CONCLUSION

APT SI showed diagnostic value for glioma grading compatible for those of ADC and rCBV. APT imaging had significant incremental value over ADC, but not over rCBV for discriminating high grade from low grade gliomas. APT SI was positively correlated with Ki-67 index. Also, we experimentally confirmed that APT SI correlated more with protein concentration than pH. Our results suggests the potential of APT imaging as a useful noninvasive imaging biomarker of glioma, including decisions for surgical sampling sites and therapeutic strategy.

ABSTRACT(IN KOREAN)

성인 Diffuse glioma 의 조직병리학적 등급 평가에 대한 Amide proton transfer imaging 의 가치 : Dynamic susceptibility contrast-enhanced MRI 및 Diffusion weighted imaging 과의 비교 및 이에 대한 추가적 가치

<지도교수 이승구>

연세대학교 대학원 의학과

최윤성

목적 : Amide proton transfer (APT) 은 chemical exchange saturation transfer 의 한 종류로서 조영제 주입 없이 peptide 및 protein 농도를 반영하는 새로운 기법이다. 이 연구에서는 APT value가 성인 diffuse glioma의 조직병리학적 등급에 따라 어떻게 변하는지 알아보고, 더불어 조직병리학적 등급에 대한 APT value의 진단적 가치를 dynamic susceptibility contrast-enhanced (DSC) MRI의 relative cerebral blood volume (rCBV) 및 diffusion weighted imaging (DWI)의 apparent diffusion coefficient (ADC)의 그것과 비교하고, 더불어 rCBV 혹은 ADC에 더한 APT value의 추가적 진단적 가치를 고찰하였다.

재료 및 방법: 이 연구는 수술 전 APT weighted imaging 을 시행한 39명의 조직병리학적으로 확인된 diffuse glioma 환자를 대상으로 하였으며, 이중 23명은 수술 전 DSC MRI와 DWI를 시행하였다. Regions of interest 는 APT, rCBV map 에서의 높은 signal 부위, 그리고 ADC map의 낮은 signal 부위에 수동으로 지정하였다. APT signal은 WHO grade 혹은 low vs high grade glioma 에 따라 비교하였다. Receiver

operative characteristic (ROC) analysis를 이용하여, APT value의 Low grade와 high grade를 구분하는 진단적 가치를 ADC 및 rCBV의 그것과 비교하였고, integrated discrimination index를 이용하여 ADC 혹은 rCBV에 더한 APT value의 추가적 진단적 가치를 분석하였다. 또한, APT value와 Ki-67 labeling index (LI)와의 관계를 linear regression으로 분석하였다.

결과: APT SI는 grade II glioma는 $0.82 \pm 0.36\%$, grade III에서는 $1.73 \pm 0.86\%$, grade IV 에서는 $2.62 \pm 0.78\%$ 로 각 grade 별로 유의미한 차이가 있었다. ($p < 0.05$ for all comparisons) Low grade 와 high grade glioma를 구분하는 진단적 능력은 APT SI, ADC, rCBV사이에 유의미한 차이가 없었으며, area under ROC curve (AUC)값은 APT 는 0.890, ADC는 0.917, rCBV는 0.947 이었다. APT 의 추가적 진단적 가치는 ADC에 더하였을 때 유의미하였으며 ($p=0.033$), rCBV에 대해서는 통계적으로 유의미하지 않았다($p=0.066$). APT SI는 Ki-67과 유의미한 상관관계를 보였다 ($p=0.001$, $R^2 = 0.26$).

결론: APT imaging은 성인의 low grade glioma와 high grade glioma의 구분에 있어 유용하며, 기존의 ADC에 대해 추가적 진단적 가치를 가지고, 또한 APT SI는 Ki-67과 유의미한 상관관계를 가지는 것으로 사료된다.
