Purpose

The purpose of this study is to investigate dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) and plasma cytokines and angiogenic factors (CAFs) as pharmacodynamic and prognostic biomarkers of bevacizumab monotherapy in colorectal cancer with liver metastasis (CRCLM).

Materials and Methods

From July 2011 to March 2012, 28 patients with histologically confirmed CRCLM received bevacizumab monotherapy followed by combined FOLFOX therapy. The mean age of the patients was 57 years (range, 30 to 77 years). DCE-MRI (K^{trans} and IAUC_{60}) was performed at baseline, first follow-up (3 days after bevacizumab monotherapy), and second follow-up (3 days after combined therapy). CAF levels (vascular endothelial growth factor [VEGF], placental growth factor [PIGF], and interleukin-8) were assessed on the same days. Progression-free survival (PFS) time distributions were summarized using the Kaplan-Meier method and compared using log-rank tests.

Results

The median PFS period was 11.2 months. K^{trans} , IAUC_{60} , VEGF, and PIGF values on the first follow-up day were significantly different compared with baseline values. No differences were observed on the second follow-up day. A > 40% decrease in K^{trans} from baseline to first follow-up was associated with a longer PFS (hazard ratio, 0.349; 95% confidence interval, 0.133 to 0.912; $p=0.032$). Changes in CAFs did not show correlation with PFS time.

Conclusion

DCE-MRI parameters and CAFs are pharmacodynamic biomarkers of bevacizumab for CRCLM. In our study, change in K^{trans} at 3 days after bevacizumab monotherapy was a favorable prognostic factor; however, the value of CAFs as a prognostic biomarker was not found.

Bevacizumab, Colorectal neoplasms

Introduction

The combination of bevacizumab with cytotoxic chemotherapy has been proved to have survival benefits in patients with metastatic colorectal cancer [1-3]. This combination has been approved by the US Food and Drug Administration (Washington, DC) as a first-line treatment [2]. Bevacizumab is an inhibitor of vascular endothelial growth factor (VEGF). It normalizes the abnormal vascular structures in tumor stroma, decreases the elevated interstitial pressure in tumors, and alleviates the hypoxic tumor microenvironment [4]. In addition to the direct antiangiogenic effects, these changes also increase chemotherapeutic efficacy. The standard protocol uses combination therapy with cytotoxic agents but does not include bevacizumab mono-therapy [2]. One major issue for the combination therapy is that clinicians cannot distinguish the effects of bevacizumab alone from the effects of the cytotoxic agents used in the protocol. Despite the benefit of bevacizumab on clinical outcome, a substantial number of patients do not respond to the therapy targeting VEGF, or they develop resistance to the drug over time. There is also an increased chance of serious side effects (e.g., stroke and gastrointestinal perforation) in patients treated with VEGF-targeted therapy [2,5]. In addition, the target agents are expensive. There is a critical need for identification of reliable biomarkers for prediction of tumor response to treatment and to predict which patients are likely to benefit from bevacizumab.

Plasma cytokines and angiogenic factors (CAFs) are potential biomarkers that reflect the systemic condition of patients with colorectal cancer treated with bevacizumab combined with cytotoxic chemotherapy [6]. Elevated baseline interleukin 8 (IL-8) is associated with a shorter progression-free survival (PFS) time. Levels of some plasma CAFs associated with angiogenesis and myeloid recruitment increase compared to baseline, before radiographic progression [7]. Plasma CAFs could be potential biomarkers of response and resistance to bevacizumab, but they cannot reflect the local response of the tumor microenvironment and cannot differentiate the response of the tumor from that of the host tissue [7].

Unlike plasma CAFs used as systemic biomarkers, an imaging biomarker can reflect local tumor condition. However, tumor size may not be a reliable marker for assessment of the early effects of antiangiogenic agents because many of these new drugs act directly on endothelial cells, not on the tumor cells. Therefore, the effects of the agents are expected to be primarily cytostatic rather than cytotoxic [8]. As an alternative functional modality, dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) is a noninvasive and appropriate method for evaluating the efficacy of these

antiangiogenic therapies using changes in tumor vascular perfusion, vascular permeability, and interstitial and intravascular volumes, without exposure to ionizing radiation [8]. The volume transfer constant (K^{trans}) and the initial area under the gadolinium concentration-time curve (IAUC) have been proposed as useful parameters that reflect the vascular response [8]. These parameters can be used with DCE-MRI to quantify the effects of antiangiogenic therapy during the early response period.

Several studies have reported reduction in K^{trans} within a few days of bevacizumab treatment [8,9]. Some studies of bevacizumab in colorectal cancer suggest that DCE-MRI may be related to clinical outcome [10,11]. In addition, several studies of anti-VEGF tyrosine kinase inhibitors have shown that reduction in K^{trans} and/or IAUC may distinguish responders from non-responders [12-14]. Based on those studies, patients with a smaller change in K^{trans} are predicted to have a shorter PFS time and to receive less clinical benefit from the treatment. However, when applying the results in the clinical practice setting, the clinician must determine whether the patients should stop receiving only bevacizumab, only the cytotoxic agent, or both bevacizumab and the cytotoxic agent. This is because the clinician cannot determine whether the change in K^{trans} results from the effect of the bevacizumab alone, the cytotoxic agent, or both.

To gain insight into the mechanisms of action and the pure effects of bevacizumab, we designed an exploratory trial with a single-arm of bevacizumab monotherapy followed by combined therapy. The effects of bevacizumab alone on both tumor physiology and systemic response were evaluated by measuring DCE-MRI parameters and plasma CAF levels. The primary objective of this phase II clinical trial was to determine prognostic biomarkers of bevacizumab alone that might show correlation with clinical outcomes. Our study also revealed the antiangiogenic effect of bevacizumab monotherapy on local tumor response using changes in DCE-MRI, and on systemic response using changes in plasma CAFs.

Materials and Methods

This study was registered at <http://www.clinicaltrials.gov> (NCT01318239). The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice Guidelines. Protocol approval was obtained from the Institutional Review Board of Severance Hospital, Yonsei University College of Medicine (Seoul, Korea). Written informed consent was obtained from each patient.

1. Patient population

Patients aged ≥ 20 years with histologically confirmed colorectal cancer and one or more measurable hepatic metastases ≥ 2 cm diameter were enrolled in the study.

Patients with standard contraindications for MRI and/or gadolinium-based contrast agents, pregnant or breast-feeding women, and patients with decreased renal function (creatinine > 1.5 mg/dL, blood urea nitrogen > 30 mg/dL), who had prior chemotherapy, concurrent malignancies or significant medical comorbidities, and who had received any treatment as part of a clinical trial were excluded from the study.

2. Study design

In this single group, exploratory trial, patients were treated with bevacizumab (5 mg/kg intravenous) alone on day 1, followed by a concurrent FOLFOX-6+B regimen (bevacizumab/oxaliplatin/5-fluorouracil/leucovorin) on day 7. Reduction in dose of the cytotoxic chemotherapy was required for grade 3 or 4 toxicities that were adverse events of however, the dose of bevacizumab, was not reduced. Adverse events were graded using the National Cancer Institute Common Terminology Criteria for Adverse Events ver. 3.0. Treatment was continued until documentation of unacceptable toxicities, disease progression, or withdrawal of consent.

DCE-MRI and blood sampling for plasma CAFs were performed on the day before treatment was initiated (baseline), on day 3 after the patients received bevacizumab monotherapy (first follow-up), and on day 3 after receiving the combined chemotherapy (second follow-up) (Fig. 1).

The primary endpoint was the correlation between the changes in DCE-MRI parameters (from baseline to 3 days after administration of bevacizumab monotherapy) with PFS time. The standard DCE-MRI parameters (K^{trans} and IAUC_{60}) were measured during each imaging and the changes from baseline to first follow-up and from first follow-up to second follow-up were calculated. The baseline values were dichotomized according to the low and high group based on the median value. The changes in the DCE-MRI parameters were dichotomized according to larger and smaller change groups, using a 40% change as the cut-off value. This cut-off value of 40% was chosen because a 40% reduction in K^{trans} is necessary before a favorable clinical response can be detected [11-13,15,16]. Dichotomized values of the baseline and the changes were correlated with PFS. The changes in tumor size were also measured at baseline, first follow-up, and second follow-up.

The secondary endpoints included the correlation between changes in plasma CAFs from baseline to 3 days after beva-

cizumab monotherapy, with PFS and toxicity. For correlation with clinical outcomes, plasma CAF values were dichotomized by calculating optimal cut-off values, obtained from receiver operating characteristic curve analysis.

PFS was defined as the period from the enrollment date until the documented tumor progression date. Data were censored for the patients who were alive without disease progression at the last follow-up date. Computed tomography (CT) examination with contrast enhancement was performed before and every 3 months after treatment. Tumor response evaluated at 3 months after the treatment was dichotomized according to a partial response group and a stable disease or disease progression group. Assessment of tumor response was performed in accordance with the Response Evaluation Criteria in Solid Tumors (RECIST) ver. 1.1 guidelines [17].

3. DCE-MRI study

For reproducibility, consistent DCE-MRI methods were followed using a 3-T MR scanner (MAGNETOM Tim Trio, Siemens Healthcare, Erlangen, Germany) equipped with 8-channel body phased-array coils (Siemens Healthcare). Each patient fasted for at least 4 hours before the scan was performed.

T_1 mapping was obtained before acquisition of perfusion images to convert signal intensities of perfusion images into gadolinium concentration values. T_1 maps were calculated from two flip angle scans using 2° and 14° :

$$S(\alpha, T_1, TR) = S_0 \frac{\text{Sin}(\alpha(1 - \exp(-TR/T_1)))}{1 - \cos(\alpha) \exp(-TR/T_1)}, T_1(t) = T_{10} + r_1 * c(t),$$

where $T_1(t)$: T_1 dynamic; T_{10} : T_1 before contrast; r_1 : T_1 relaxivity of the contrast agent; and $c(t)$: contrast agent concentration.

Axial images for the T_1 maps were obtained using three-dimensional (3D) spoiled gradient echo sequences with two different flip angles (2° and 14°) and a fixed repetition time/echo time (TR/TE; 4.91 msec / 1.71 msec). A total of 20 slices per sequence using a different flip angle were acquired. The slice thickness was 3.6 mm and the in-plane resolution was 1.67×1.67 mm² for each in one breath-hold and scan time of 18 seconds.

Perfusion images were obtained using 3D T_1 -weighted time resolved angiography with stochastic trajectories (TWIST) sequence (TR/TE, 4.51 msec / 1.76 msec; slice thickness, 3.6 mm; flip angle, 12° ; matrix size, 192×138 ; field of view, 300 mm; band width, 250 Hz/Px). Serial images (temporal resolution, 0.295 seconds) were acquired during shallow, free-breathing respiration. Twenty axial image slices

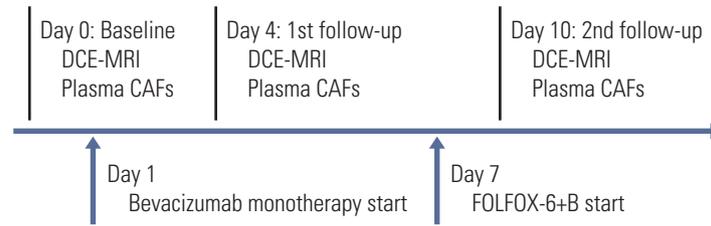

Fig. 1. Study design. Dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) studies and blood sampling for plasma cytokine and angiogenic factors (CAFs) were performed 1 day before treatment (day 0). Patients were treated with bevacizumab (5 mg/kg intravenously) alone on day 1 and the first follow-up DCE-MRI and blood sampling for plasma CAFs were performed 3 days after the monotherapy treatment (day 4). A concurrent FOLFOX-6+B regimen (bevacizumab/oxaliplatin/5-fluorouracil/leucovorin) was administered on day 7 and the second follow-up DCE-MRI and blood sampling for plasma CAFs were performed 3 days after combined chemotherapy (day 10).

(range, 10 cm) per cycle were obtained while centered on the center of the tumor (5.9 seconds for one cycle). Perfusion images were acquired repetitively over 75 cycles for 7-8 minutes. A total volume of 15 mL Omniscan (gadodiamide, GE Healthcare, Oslo, Norway) was used as a contrast material, and was injected intravenously using an automatic injector at a rate of 5 mL/sec, followed by a 30-mL saline injection. An algorithm with a diffeomorphism flow was introduced for registration between the T1 mapping sequence and the perfusion imaging sequence. The algorithm was based on maximization of statistical similarity criteria (local and global) in a variational framework. This flow was adjusted using a template propagation method by composition of small displacements. Regularization was achieved using fast filtering techniques. This approach combined the robustness of statistical similarity measures with the flexibility of diffeomorphic matching techniques [18].

A commercial post-processing software based on a modified Tofts model (Tissue 4D, Siemens Medical Solutions) and installed at an image processing workstation (Leonardo, Siemens Medical Solutions), was used for calculation of the quantitative perfusion parameters. Motion correction was performed using the non-rigid body algorithm on the post-processing software. For analysis of the perfusion data, the arterial input function was set as the average bi-exponential function using fast mode. Color-coded maps of the K^{trans} values were acquired through data processing. IAUC_{60} values for the first 60s from the contrast injection were also acquired. Two dimensional regions of interest (ROIs) were hand-drawn on post-processed images by an abdominal radiologist with 7 years experience, according to the tumor margin through the midline of the z-axis of the tumor in the section where the largest transverse diameter of liver metastasis was detected. ROIs were drawn for all tumors > 2 cm in diameter and a mean value for K^{trans} was estimated for all patients with

multiple lesions. Unlike RECIST, the commonly used criterion for measurable lesions on DCE-MRI is > 2 cm in diameter, in consideration both of size reduction and measurement error [10].

The baseline K^{trans} and IAUC_{60} values were acquired from the baseline study results. The values for these same parameters were assessed from the first follow-up and second follow-up images. The changes were calculated as absolute and percentage values.

4. Plasma sample collection and analysis

Blood samples were collected for circulating pharmacodynamics marker studies prior to the initial bevacizumab infusion, on the third day after bevacizumab monotherapy, and on the third day after combined therapy. Serum samples were assayed for circulating VEGF-A, placental growth factor (PIGF), soluble vascular endothelial growth factor receptor 2 (sVEGFR2), and IL-8 using enzyme-linked immunosorbent assay kits (R&D Systems, Minneapolis, MN). The changes were calculated as absolute and percentage values.

5. Statistical analysis

DCE-MRI parameter and plasma CAF values were correlated with PFS. Baseline values and the changes in the DCE-MRI parameters and CAF values were analyzed to determine correlations among the parameters.

Kaplan-Meier estimates and log-rank tests were computed to evaluate the associations between changes in DCE-MRI parameter or plasma CAF values with the length of PFS or overall survival (OS). Analyses of associations between baseline values of DCE-MRI parameters or plasma CAFs with PFS or OS were also performed.

The PFS and OS times were estimated using the Kaplan-

Meier method. The differences among the patient groups for PFS, OS, and treatment response were compared using multivariate Cox regression analysis. Six parameters were considered as possible covariates in the regression analysis. The associations among the categorical variables and the continuous variables were analyzed using chi-square tests and linear mixed models, respectively.

For all analyses, a p -value < 0.05 was considered statistically significant. SPSS ver. 18.0 (SPSS Inc., Chicago, IL) and SAS ver. 9.2 (SAS Institute Inc., Cary, NC) were used for all analyses.

Results

1. Patient characteristics and clinical outcomes

Thirty-two patients were enrolled in the study between July 2011 and March 2012. Four patients were excluded from the analysis due to follow-up loss ($n=3$) or imaging error ($n=1$). The mean age of the patients was 57 years (range, 30 to 77 years), and a total of 60 hepatic metastatic lesions in patients with rectal cancer ($n=8$) and colon cancer ($n=20$) were analyzed. The Eastern Cooperative Oncology Group performance status score was 0 for 22 patients and 1 for six patients. The mean baseline carcinoembryonic antigen value was 340.78 ng/mL.

The median PFS time was 11.2 months (95% confidence interval [CI], 6.9 to 15.5), and the median OS time was 22.7 months (95% CI, 18.8 to 26.7).

In assessment of tumor response on 3-month follow-up CT images according to RECIST ver. 1.1, 13 patients showed partial response and 14 patients showed stable disease. Only one patient showed disease progression on the 3-month follow-up. Dose reduction was required for five of 28 patients due to toxicity during the course of the scheduled treatment. Fatigue and neuropathy were the most common adverse events. Neutropenia was the most frequent of the grade 3 or 4 adverse events (Table 1).

2. DCE-MRI parameters and plasma CAFs as pharmacodynamic biomarkers

The results for the changes in DCE-MRI parameters, plasma CAF values, and tumor size at 3 days after bevacizumab monotherapy (first follow-up) and at 3 days after combined chemotherapy (second follow-up) are shown in Fig. 2. Compared with the baseline values, the K^{trans} , IAUC₆₀, and serum VEGF values at the first follow-up evaluation had decreased ($p < 0.05$). No significant changes were detected

at the second follow-up evaluation compared to the first follow-up. Serum PIGF was elevated at the first follow-up evaluation and was still elevated at the second follow-up evaluation. There were no significant changes in sVEGFR2, IL-8, and size, and no significant correlations were observed between the changes in DCE-MRI parameters and plasma CAF values.

The mean tumor size measured at baseline, first follow-up, and second follow-up was 47.0 ± 22.0 mm, 47.0 ± 21.3 mm, and 47.0 ± 22.1 mm, respectively.

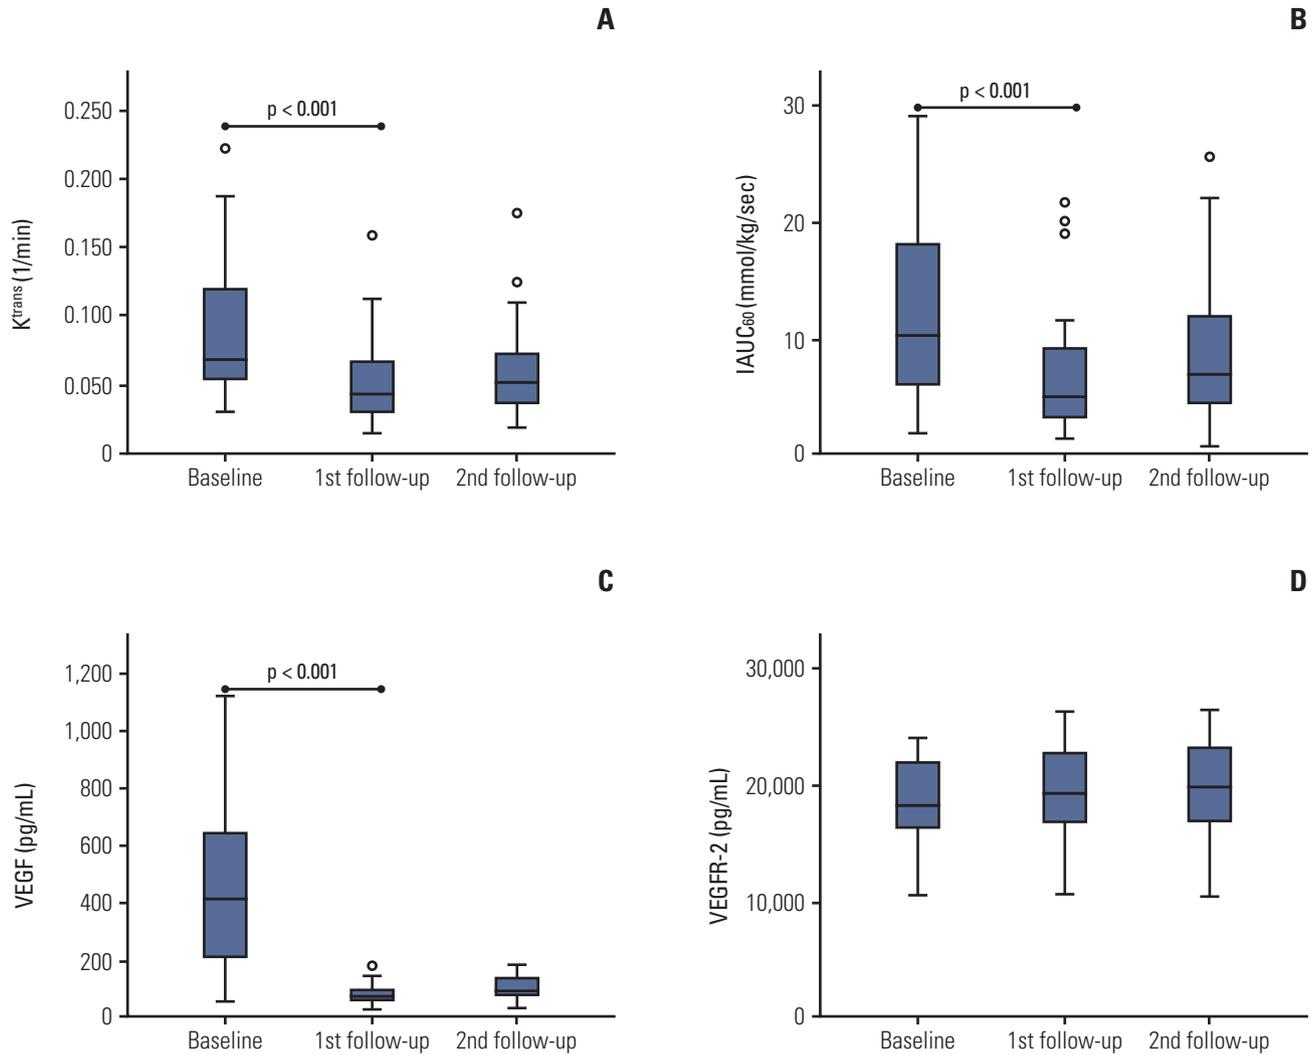

Fig. 2. (A-G) Changes in the values of the dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) and plasma cytokine and angiogenic factors (CAFs) parameters from baseline, first follow-up after treatment with bevacizumab alone, and second follow-up after treatment with combined therapy. 3. DCE-MRI parameters and plasma CAFs as prognostic biomarkers

The results using Kaplan-Meier analysis indicated that PFS time showed correlation with the dichotomized K^{trans} (i.e., with the cut-off set at 40% reduction) variable. A $\geq 40\%$ reduction in K^{trans} from baseline to 3 days after bevacizumab monotherapy showed significant association with a longer PFS time ($p=0.025$). OS time did not show significant association with the reduction in K^{trans} . The changes in the other parameters, including $IAUC_{60}$ and plasma CAFs, did not show significant correlation with PFS time (Fig. 3).

When dichotomized at the median values for the baseline DCE-MRI parameters, a high baseline $IAUC_{60}$ (cut-off value, 10.337) showed significant association with a longer PFS time ($p=0.033$), but not with a longer OS time (Fig. 3). In analysis of the relationships between plasma CAFs and clinical outcomes, there were no associations between baseline serum markers and PFS or OS times.

In multivariate analyses using the Cox regression method, a greater reduction in K^{trans} and a high baseline $IAUC_{60}$ were independent predictors for PFS time. Patients with a $\geq 40\%$ reduction in K^{trans} from baseline to 3 days after bevacizumab monotherapy had a 0.349 times lower hazard of disease pro-

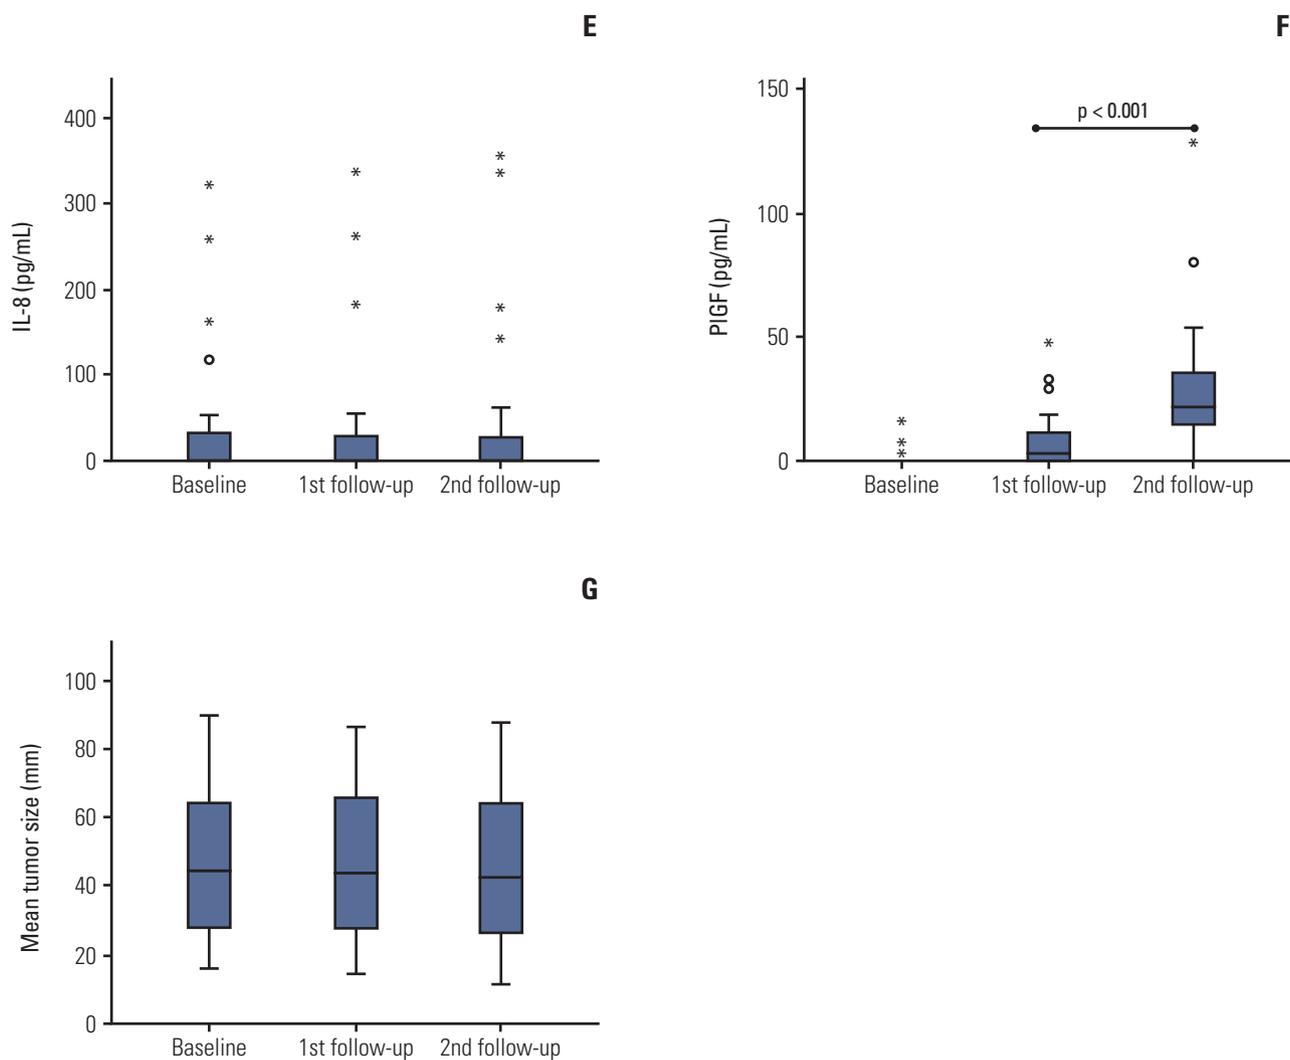

Fig. 2. (Continued from the previous page)

gression (Table 2).

The combined effects of changes in K^{trans} and baseline $IAUC_{60}$ were also analyzed. The results using the Kaplan-Meier method indicated that the patients with both a greater change in K^{trans} and a higher baseline $IAUC_{60}$ experienced the longest median PFS time (23.8 months, $n=7$); the patients with both the smaller change in K^{trans} and the lower baseline $IAUC_{60}$ values had the shortest median PFS times (8.1 months, $n=10$, $p=0.019$). In multivariate analysis, compared with the patients with the greater change in K^{trans} and higher baseline $IAUC_{60}$ values, the patients with the smaller change in K^{trans} and the lower baseline $IAUC_{60}$ values had a six times greater odds of disease progression (hazard ratio [HR], 6.061; 95% CI, 1.591 to 23.09; $p=0.008$). The differences in OS times were not significantly different (HR, 2.497; 95% CI, 0.643 to

9.698; $p=0.186$).

In multivariate analysis for treatment response at a 3-month follow-up CT, a $\geq 40\%$ reduction in K^{trans} from the baseline to 3 days after bevacizumab monotherapy ($p=0.013$) and a higher baseline $IAUC_{60}$ ($p=0.033$) were statistically significant independent predictors for a better response to the therapy (Fig. 4).

No significant correlation was observed between change in K^{trans} with PFS (Pearson correlation coefficient [r], -0.298 ; $p=0.124$) and baseline $IAUC_{60}$ with PFS (Pearson correlation coefficient [r], -0.270 ; $p=0.165$).

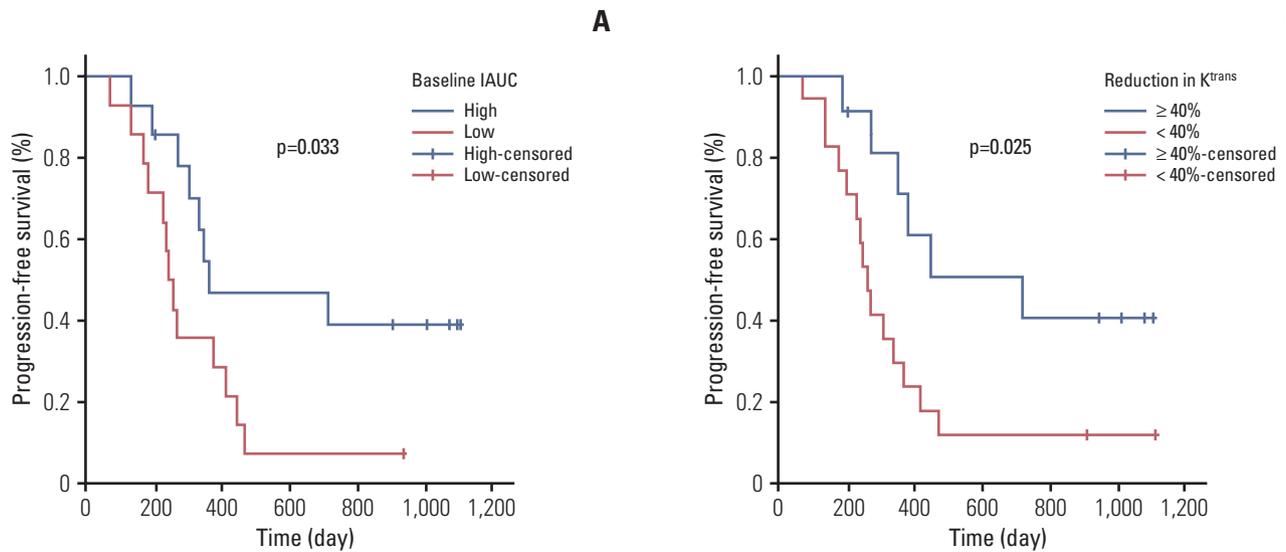

Fig. 3. Kaplan-Meier estimates for progression-free survival time for patients with low and high baseline IAUC₆₀ values (A), and a K^{trans} reduction at the first follow-up (B).

Discussion

The OS time of 22.7 months and the PFS time of 11.2 months obtained in our study compared favorably with the OS time of 21.3 months and the PFS time of 10.4 months obtained in a previous randomized controlled phase III trial using concurrent FOLFOX-6+B regimen [1]. Although our study was limited by the exploratory single-arm trial study design, this result suggested that bevacizumab monotherapy followed by concurrent FOLFOX-6+B regimen is comparable to a concurrent FOLFOX-6+B regimen for treatment of colorectal cancer liver metastasis (CRCLM).

The results from this exploratory trial suggested that the patients with $\geq 40\%$ reduction in K^{trans} by 3 days after bevacizumab monotherapy had a significantly longer PFS time, suggesting that they received a clinical benefit from bevacizumab that those with a $< 40\%$ change in K^{trans} did not receive. The results might imply that the prognosis for combined chemotherapy using bevacizumab can be predicted by the microvascular changes induced by bevacizumab alone. The change was detected as early as 3 days after bevacizumab monotherapy, which is much earlier than the size reductions induced by the combined therapy. Therefore, the decision to continue with bevacizumab, or not, can be made as early as 3 days after administration of bevacizumab monotherapy, with minimal cost or side effects. This result was consistent with the results of previous studies reporting that K^{trans} can be used as a prognostic biomarker that reflects

microvascular change after antiangiogenic therapy, even when the target tumors, the drugs used, or the day that DCE-MRI results are obtained (usually 14 days after treatment) are different [9,11,12,19-21]. Our study results support the hypothesis that DCE-MRI can be used as a prognostic biomarker for the bevacizumab therapy used for CRCLM treatment.

Based on the results of our study, baseline IAUC₆₀ values can be used as a prognostic biomarker for the outcome of therapy using bevacizumab. This study found that patients with a higher than median value baseline IAUC₆₀ had a significantly longer PFS time, suggesting that they could receive clinical benefit from combined therapy using bevacizumab.

The power as a prognostic biomarker is greater when considering the change in K^{trans} combined with the baseline IAUC₆₀ value, compared with the values considered separately. A patient with a $\geq 40\%$ change in K^{trans} by 3 days after bevacizumab therapy and a relatively high baseline IAUC₆₀ should benefit from combined therapy with bevacizumab.

This study found that all of the DCE-MRI parameters (K^{trans} and IAUC₆₀) decreased significantly by 3 days after bevacizumab monotherapy, but not after combined chemotherapy (maintaining the lower level as similar to that at 3 days after bevacizumab monotherapy).

These results reflected the fact that perfusion changes in the patients with CRCLM were induced by bevacizumab alone, but not by combined chemotherapy. When used for the treatment of human rectal cancer, the direct effects of bevacizumab on tumor physiology include decreases in

Table 2. Results of multivariate analyses of the predictors of progression-free survival

Variable	HR (95% CI)	p-value
K ^{trans} _baseline	0.716 (0.301-1.705)	0.451
K ^{trans} 1st follow-up_baseline	0.349 (0.133-0.912)	0.032
IAUC ₆₀ _baseline	0.39 (0.159-0.957)	0.040
IAUC ₆₀ 1st follow-up_baseline	1.014 (0.425-2.42)	0.975
VEGF_baseline	1.217 (0.508-2.915)	0.660
VEGF 1st follow-up_baseline	1.68 (0.224-12.589)	0.614
VEGFR-2_baseline	0.523 (0.216-1.268)	0.151
VEGFR-2 1st follow-up_baseline	4.328 (0.912-20.532)	0.065
IL-8_baseline	-	-
IL-8 1st follow-up_baseline	0.613 (0.205-1.833)	0.381
PIGF_baseline	-	-
PIGF 1st follow-up_baseline	1.034 (0.303-3.53)	0.957

The median baseline values for IL-8 and PIGF were zero, thus the baseline covariates of those parameters were excluded from the multivariate analyses. The group with the lower baseline value, compared with the median value, was the baseline reference group. The group with a < 40% change was the reference group for the analysis of the change in values over time. If the change between the first follow-up and the second follow-up was not significant for a parameter, it was excluded from the multivariate analysis. HR, hazard ratio; CI, confidence interval; VEGF, vascular endothelial growth factor; IL, interleukin; PIGF, placental growth factor.

tumor blood perfusion, blood volume, interstitial fluid pressure, and microvessel density [22,23]. These effects are induced by a direct antipermeability effect, vasoconstriction, a direct antiangiogenic effect inhibiting the formation of immature vessels, and/or apoptosis of proliferating endothelial cells [8]. Since the development of antiangiogenic therapy, perfusion imaging has been extensively investigated as a method for use in validation of the biologic efficacy of the molecular target agents on tumor tissue. DCE-MRI, one of the imaging modalities for perfusion imaging, is advantageous for the quantitative measurement of tumor microcirculation *in vivo*. This approach is noninvasive, repeatable, without radiation hazards, and includes anatomic details of the tumor. Because angiogenesis is a direct or indirect target of many new anticancer drugs, DCE-MRI is an appealing biomarker candidate for assessment of tumor angiogenic activity and for monitoring the effects of antiangiogenic agents [8]. Our study results indicated that DCE-MRI can be used a pharmacodynamic biomarker of bevacizumab therapy of CRCLM.

We also assessed the effects of bevacizumab on plasma CAFs (IL-8, VEGF-A, vascular endothelial growth factor receptor 2 [VEGFR-2], and PIGF) to examine the systemic response. VEGF (also referred to as VEGF-A) has a crucial role in physiological and pathological angiogenesis, and VEGF-targeted agents have been validated as providing clinical benefits in the treatment of malignant disease [22,24]. To better understand the systemic effect of bevacizumab, which

is a VEGF-targeted agent, more information about the biology of the VEGF ligand/receptor system is needed [24]. The mammalian VEGF family of ligands consists of five glycoproteins (i.e., VEGF-A [commonly referred to as VEGF], VEGF-B, VEGF-C, VEGF-D, and PIGF). The VEGF ligands bind to and activate three different type III receptor tyrosine kinases (known as VEGFR-1, VEGFR-2, and VEGFR-3), which have similar structures. Each ligand of the VEGF family has a distinctive binding specificity for one of the three receptors, therefore a diversity of functions can be mediated. VEGFR-2 is the key mediator of VEGF-induced angiogenesis [24]. Our results showed a significant decrease in circulating VEGF-A by 3 days after bevacizumab monotherapy, but not after combined chemotherapy. Most of the circulating VEGF-A was likely bound to bevacizumab as early as 3 days after bevacizumab monotherapy. This result was consistent with our predictions and with other data from blood marker studies of bevacizumab used for the treatment of colorectal cancer and other cancers [7,25].

An increase in plasma PIGF levels was observed by 3 days after bevacizumab monotherapy and a more significant increase by 3 days after combined chemotherapy. Inhibition of VEGF signaling leads to a presumed compensatory increase in expression of other angiogenic factors, resulting in resistance to VEGF-targeted therapy; PIGF levels increase in plasma following blockade of VEGF signaling [24]. The delayed response of PIGF in our study can be explained by the consequential effect of the blockade of VEGF-A with

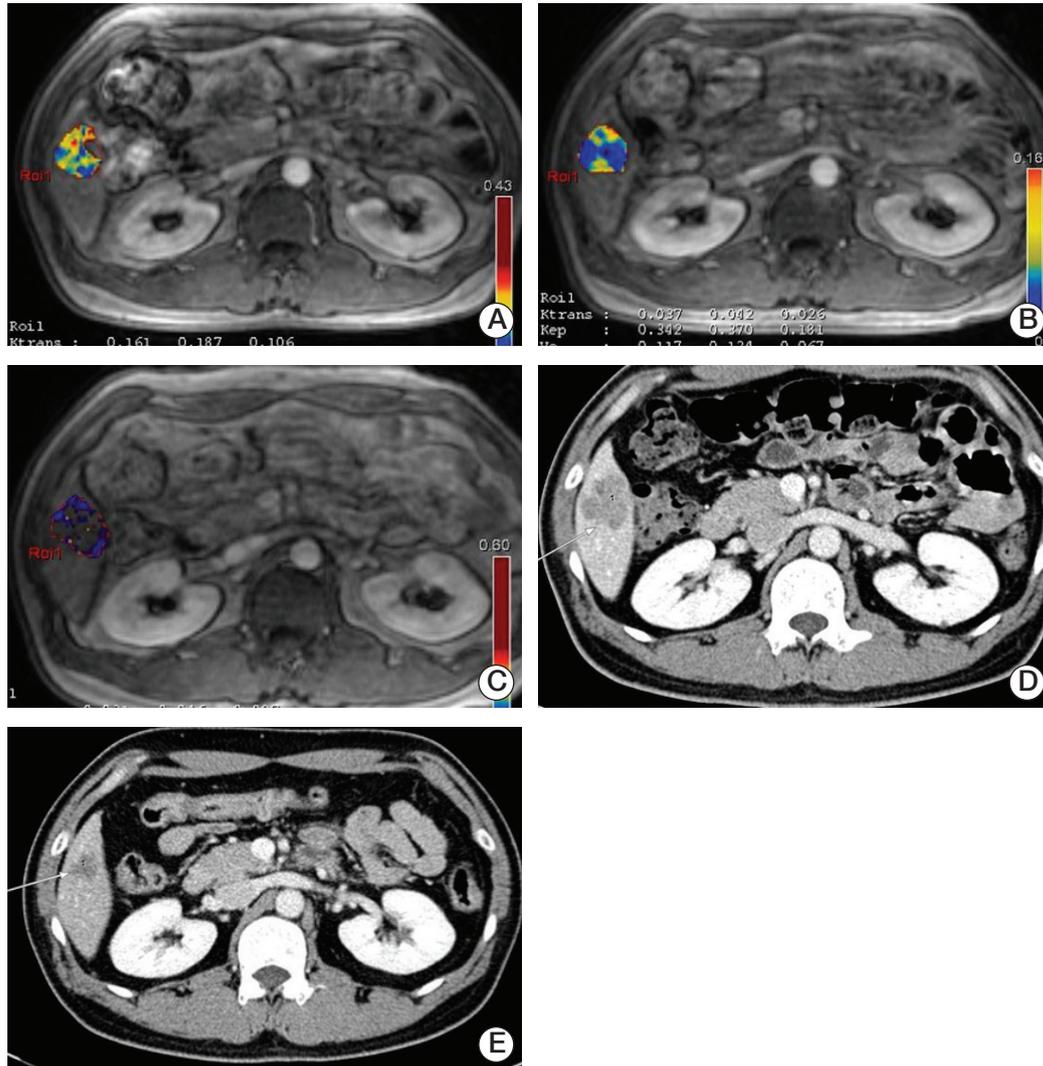

Fig. 4. A 39-year-old male patient had rectal cancer with one hepatic metastatic lesion. (A) On the baseline image the IAUC₆₀ value was 22.29, which was a higher baseline group value. The baseline K^{trans} value was 0.187. (B) On the first follow-up image after bevacizumab monotherapy, the patient had a 66% reduction in K^{trans} (0.037). The dynamic contrast enhanced-magnetic resonance imaging results indicated that there were no significant changes in the perfusion parameters between the first and second follow-up (C) (0.031). Based on the large reduction in K^{trans} , and the high baseline IAUC₆₀ level, this patient was expected to have a good response to the treatment and to have a good prognosis. Compared with the baseline computed tomography (CT) image (D), the metastatic lesion had decreased in size by the 3-month CT follow-up (E).

bevacizumab.

Kopetz et al. [7] reported that an elevated IL-8 level at baseline is associated with a shorter PFS time, but our study found no association between baseline IL-8 values and PFS time. This result could be due to the different time points used for plasma sampling, which were 3 days after treatment in our study and before progression in their study (median PFS time, 12.8 months). Circulating cytokine levels may

reflect the responses of non-neoplastic host tissue and of neoplastic tumor tissue to treatment [7]. The associations between plasma angiogenic factors and clinical outcomes remain unclear, probably due to the complexities of tumor angiogenesis, angiogenic factors, and resistance mechanisms to the anti-angiogenic therapy [6,7,24].

This study had the limitation of small sample size. Therefore, the results of our study, usefulness of K^{trans} change as a

prognostic biomarker, cannot be directly applied to the daily practice. Further study with a larger sample size is needed.

Conclusion

In conclusion, DCE-MRI parameters and CAFs are pharmacodynamic biomarkers of bevacizumab for CRCLM. In our study, change in K^{trans} at 3 days after bevacizumab monotherapy was a favorable prognostic factor, but the value of CAFs as a prognostic biomarker was not found.

Conflicts of Interest

Conflict of interest relevant to this article was not reported.

Acknowledgments

This study was supported by a grant from the National Research Foundation of Korea (7-2010-0288).
