ACKNOWLEDGEMENTS

First of all, I would like to appreciate Professor Chang Geol Lee for advising for giving me such inspiring advice and support for preparing this thesis and setting a good example for me by devoting himself to patients suffering from cancer. Also I would like to express my gratitude to professor Jaeho Cho and Mijin Yun for giving me advices which were essential for completing this article. I would like to appreciate to professor Chang-Ok Suh, Jinsil Seong, Ki Chang Keum, Ik Jae Lee, Jun Won Kim, Hong In Yoon, and Jee Suk Chang, for always offering the great instructions with careful concern. Last but not least, I really appreciate Hojin Cho for his contribution on this research.

Nalee Kim

ABSTRACT

**Prognostic values of mid-radiotherapy ^{18}F -FDG PET/CT in patients
with esophageal cancer**

(Directed by Professor Chang Geol Lee)

Purpose: To identify whether early metabolic responses as determined using ^{18}F -fluorodeoxyglucose positron emission tomography/computed tomography (FDG PET/CT) during radiotherapy (RT) predict outcomes in patients with esophageal cancer.

Materials and Methods: Twenty-one patients with esophageal cancer who received pre-treatment ^{18}F -FDG PET/CT (PET1) and mid-radiotherapy ^{18}F -FDG PET/CT (PET2) after 11 fractions of RT (median 23.1 Gy, 2.1 Gy per fraction) were retrospectively reviewed. The region of interest for each calculation was delineated using “PET Edge”. We calculated PET parameters including maximum and mean

standardized uptake values (SUV_{max} and SUV_{mean} , respectively), metabolic tumor volume (MTV), and total lesion glycolysis (TLG).

Results: After a median follow-up of 13 months, the 1-year overall and progression-free survival rates were 79.0% and 34.4%, respectively. Four patients developed locoregional recurrences (LRRs) and 8 had distant metastases (DMs). The 1-year overall LRR-free rate was 76.9% while the DM-free rate was 60.6%. The relative changes in MTV (ΔMTV) were significantly associated with LRR ($p = 0.03$). Conversely, the relative changes in SUV_{mean} (ΔSUV_{mean}) were associated with the risk of DM ($p = 0.02$). An ΔMTV threshold of 1.14 yielded a sensitivity of 60%, specificity of 94%, and an accuracy of 86% for predicting an LRR. Additionally, a ΔSUV_{mean} threshold of a 35% decrease yielded a sensitivity of 67%, specificity of 83%, and accuracy of 76% for the prediction DM.

Conclusion: Changes in tumor metabolism during RT could be to predict treatment responses, recurrences, and prognoses in patients with esophageal cancer.

I. INTRODUCTION

Cancer staging is currently the most important measure for predicting survival as well as for treatment planning. The use of ^{18}F -fluoro-2-deoxyglucose positron emission tomography/computed tomography (^{18}F -FDG PET/CT) as an imaging modality has been steadily increasing in patients with most types of solid tumors, including esophageal cancer [1]. The use of FDG uptake, which is indicative of tumor metabolism, has also been explored for its prognostic utility. ^{18}F -FDG PET/CT-based metabolic parameters such as the standardized uptake value (SUV) and total lesion glycolysis (TLG) have been established and validated as surrogate parameters for predicting survival in patients with esophageal cancer [2,3].

Additionally, ^{18}F -FDG-PET/CT can be used to evaluate treatment response by determining changes in tumor glucose uptake following chemotherapy or radiotherapy (RT). Several studies of patients with esophageal cancer have indicated that tumor metabolic activity after preoperative treatment is strongly associated with histopathologic responses and overall outcomes [4-7]. However, such assessments usually provide information regarding late treatment responses, the main drawback of which is that physicians are unable to provide patients with non-responding tumors alternative treatment strategies during the early stages of therapy. As such, other studies have demonstrated satisfactory measurements of metabolic parameters after only 2 weeks of induction therapy with acceptable sensitivities and specificities, allowing for the accurate early prediction of response to treatment in patients with esophageal cancer [8,9]. To that end, ^{18}F -FDG PET/CT has been proposed for predicting early responses and potentially allowing a change of individualized treatment; however, this method has not yet been established in routine clinical practice. Determining early responses using ^{18}F -FDG PET/CT would allow non-invasive stratification of patients according to their responses and help devise more effective treatment regimens. Most studies of early responses using ^{18}F -FDG PET/CT are limited to patients treated with chemotherapy and not RT. To implement predictive ^{18}F -FDG PET/CT-guided algorithms for patients undergoing RT, the prognostic values of early metabolic responses as well as specific ^{18}F -FDG PET/CT-based metabolic parameters ought to be determined in the setting of mid-RT ^{18}F -FDG PET/CT (PET2) after the initiation of RT. Therefore, the

aim of this study was to investigate whether mid-treatment metabolic response evaluation using ^{18}F -FDG PET/CT could be used as a predictor of RT response in patients with esophageal cancer.

II. MATERIALS AND METHODS

1. Study population

Patients diagnosed with esophageal cancer who had undergone RT with PET2 between November 2015 and June 2017 were enrolled in this study. Patients were excluded if pre-RT ^{18}F -FDG PET/CT (PET1) was either not available or performed at another institution ($n = 4$) or if they did not complete RT ($n = 2$). Ultimately, we retrospectively reviewed the medical records and tumor characteristics of 21 patients, as well as their clinical outcomes. This study was approved by the Health Institutional Review Boards of Yonsei University Hospital (IRB No. 2017-3510-001). The requirement for informed consent was waived owing to the study's retrospective nature.

2. Chemotherapy

Standard treatment at our center consists of 6 weeks of RT with concurrent chemotherapy. Chemotherapy was administered to all patients using a 5-fluorouracil (5-FU) – based regimen except in 3 patients who were medically ineligible (2 underwent RT alone and 1 received uracil/tegafur). Overall, 18 patients were treated

with the 5-FU/cisplatin regimen, 2 cycles of which were administered concurrently during RT. Patients had a 4-week break after the completion of RT, and additional maintenance chemotherapy was performed if a medical oncologist determined that the patient's performance status would allow for it. 5-FU was administered at 500–1250 mg/m² daily as a continuous infusion using a portable electronic pump on days 1–4, while cisplatin was administered at 40–100 mg/m² on day 1 and during RT sessions.

3. Radiotherapy

The consistent RT technique used was as follows: The gross tumor volume (GTV) was delineated using simulation CT (3 mm slice thickness) and included the primary tumor and involved regional nodes that were detected via PET and CT fusion using the MIM software (Mim Software Inc., Cleveland, OH, USA). The initial clinical target volume (CTV) included the GTV plus a margin of at least 4 cm longitudinally and 2 cm radially. The final planning target volume (PTV) was delineated by adding a 0.3 cm margin to both the GTV and CTV based on our institutional image-guidance strategies (PTV1 and PTV2, respectively). A total of 63 Gy in 30 fractions was prescribed to the PTV1 while 54 Gy in 30 fractions was prescribed to the PTV2 using simultaneous integrated boost for patients who underwent definite chemoradiation therapy. For preoperative chemoradiation therapy, a total of 44.1 Gy in 21 fractions and 37.8 Gy in 21 fractions were prescribed to the PTV1 and PTV2, respectively. All patients received intensity-

modulated radiation therapy using volumetric modulated arc therapy. Daily pre-treatment imaging using cone beam CT was performed with corresponding position correction before the delivery of each fraction.

4. ^{18}F -FDG PET/CT method

Prior to undergoing ^{18}F -FDG PET/CT, each patient fasted for a minimum of 6 hours before ^{18}F -FDG administration, and the plasma glucose level was maintained below 140 mg/dL. ^{18}F -FDG was administered intravenously at an approximate dosage of 5.5 MBq/kg of body weight. After a tracer uptake time of 45–60 min, patients were subjected to PET/CT imaging; a low-dose, non-contrast CT scan was obtained for attenuation correction. The intrinsic spatial resolution of the system was approximately 5 mm (full-width at half-maximum) in the center of the field of view. Images were acquired from the skull base to the proximal thigh. PET images were reconstructed using a 3D row-action maximum-likelihood iterative reconstruction algorithm. The ^{18}F -FDG PET/CT examinations were performed within 1 month before the initiation of RT (PET1) and a median 11 (range, 9–12) days after RT (PET2).

5. PET metrics

Measurements of metabolic uptake in FDG-avid tumors following pretreatment and mid-treatment scans were compared and evaluated to predict the response to RT. For analysis of PET metrics, all primary tumors were defined as the region of

interest and delineated on the PET1 and PET2 scans using PET Edge, a semi-automatic gradient-based delineation method included in MIM software, consistently by a single radiation oncologist (NLK). This method algorithm places the contour boundary at the location where the signal gradient is highest; it has been found to correspond better to pathological specimens than threshold-based methods [10] and has recently been validated in a multi-observer study that showed superiority over the manual and threshold methods in non-small cell lung cancers [11].

The following quantitative features were extracted from the regions of interest of the PET1 and PET2: maximum and mean SUVs (SUV_{max} and SUV_{mean} , respectively), metabolic tumor volume (MTV), and TLG. The SUV_{max} was defined as the maximum activity concentration in the tumor/(injected dose/body weight). The SUV_{mean} was defined as the mean concentration of FDG in the tumor/(injected dose/body weight). The MTV was automatically calculated by the software by summing the areas with each 2-dimensional transverse tumor contour and multiplying the values by the corresponding slice thickness. The TLG was calculated by multiplying the SUV_{mean} by the MTV of the tumor [12].

6. Statistical analysis

The association between clinical outcomes and PET metrics was evaluated using the chi-square test for categorical parameters and Student's T-test for continuous parametric parameters. Multiple PET parameters were logarithmically transformed

to meet the assumption of linearity on the logit scale. The relative changes (%) were calculated using the logarithmically transformed parameter values for the PET1 and PET2 scans. Locoregional recurrence and distant metastasis were defined as recurrence within and outside the PTV, respectively. The time to events was measured from the date of the first RT administration. The survival curves were estimated using the Kaplan-Meier method and compared using the log-rank test. Multivariate analysis of locoregional recurrence and distant failures were performed using Cox regression analysis. After identifying statistically significant PET parameters for discriminating responders from non-responders, receiver operating characteristics (ROC) curve analyses were used to assess the potentials of the studied PET parameters; the sensitivity, specificity, accuracy, positive predictive value (PPV), and negative predictive value (NPV) were calculated for an optimal threshold that was determined by providing equal weight to the sensitivity and specificity on the ROC curve. A p-value <0.05 was considered statistically significant. Statistical analyses were performed using SPSS version 23.0.0 (IBM Corp., Armonk, NY) and R version 3.3.0.

III. RESULTS

1. Cohort characteristics

The patients' characteristics are shown in Table 1. Most subjects underwent definitive chemoradiation therapy (n = 17, 81.0%). The PET2 was

obtained approximately 2 weeks (median, 11 days) after the initiation of RT; the median dose at the time of PET2 was 23.1 (range, 18.9–25.2 Gy).

2. PET metrics

The median PET1 SUV_{max} and SUV_{mean} were 15.1 (IQR 9.9–19.5) and 7.7 (IQR 5.8–11.5), respectively. Furthermore, the median PET1 MTV and TLG values were 10.2 (IQR 7.3–19.0) mL and 96.2 (IQR 39.7–346.3), respectively. The PET metrics were generally lower on PET2 than on PET1; the per-patient relative changes after RT according to ^{18}F -FDG PET intensity (SUV_{max} , SUV_{mean}) and metabolic tumor volume (MTV, TLG) are shown in Table 2.

Table 2. Quantitative parameters on the pre-treatment PET1 scan and mid-radiotherapy PET2 scan

| | PET 1 | | PET 2 | | % of decrease | |

FDG PET/CT; IQR, interquartile range; SUV_{max} , maximum standardized uptake value; GTV, gross tumor volume; SUV_{mean} , mean standardized uptake value; MTV, metabolic tumor volume; TLG, total lesion glycolysis

3. Treatment outcomes

The median follow-up was 13.1 (range, 1.6–23.6) months. The 1-year overall survival (OS) and progression-free survival (PFS) rates were 79.0% and 34.4%, respectively (Fig. 1A). Four patients developed locoregional recurrences and 8 showed distant metastases. The overall 1-year locoregional recurrence-free rate (LRFR) was 76.9%, while the distant metastasis-free rate (DMFR) was 60.6% (Fig. 1B).

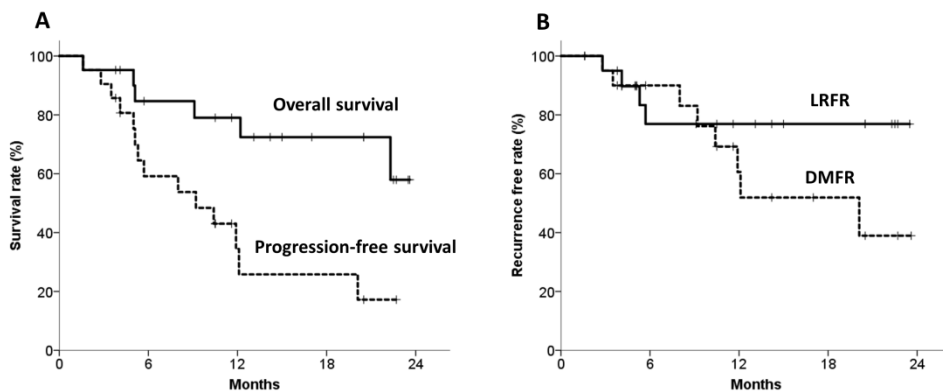

Figure 1. Progression-free survival, overall survival (A), locoregional recurrence-free rate (LRFR), and distant metastasis-free rate (DMFR) (B) for the entire cohort.

4. Prognostic PET parameters

The relative changes to the MTV (i.e., Δ MTV) were significantly associated with locoregional recurrence (hazard ratio [HR] 0.98, 95% confidence interval [CI] 0.96–1.00; $p = 0.03$, Table 3). Conversely, the relative changes in the SUV_{mean} (i.e., Δ SUV_{mean}) were associated with the risk of distant metastasis (HR 0.90, 95% CI 0.82–0.99; $p = 0.02$, Table 3). However, neither initial GTV, mid-RT GTV, nor relative changes to the GTV was associated with locoregional recurrence or distant metastasis.

Table 3. Prognostic factors of locoregional recurrence and distant metastasis identified using a Cox proportional hazards model.

| | Locoregional recurrence | | | Distant metastasis | | |
|----------------------------|-------------------------|--------------------|---------|---------------------|-------------|---------|

5. Good responders and non-responders

The optimal ΔMTV and $\Delta\text{SUV}_{\text{mean}}$ cut-off values that discriminated responders from non-responders were calculated as 1.14 (MTV PET2/MTV PET1) and -35% (i.e., a 35% decrease), respectively.

The LRFRR was more favorable in responders as determined by ΔMTV ($n = 16$, 76.2%) than in non-responders ($n = 5$, 23.8%), with 1-year LRFRRs of 92.3% and

0.0%, respectively ($p < 0.001$, Fig. 2A). Distant metastasis was not significantly different between these 2 groups; the 1-year DMFRs were 60.3% vs. 75.0%, respectively ($p = 0.896$, Fig. 2B).

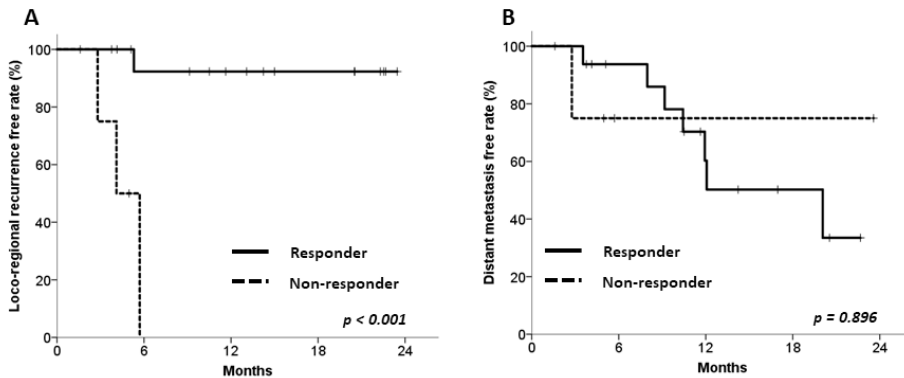

Figure 2. Loco-regional recurrence-free rate (A) and distant metastasis-free rate (B) of patients according to the metabolic tumor volume (MTV) reduction ratio (mid-treatment MTV-to-pretreatment MTV). Responders were patients with MTV reduction ratios ≤ 1.14 ; while non-responders were patients with MTV reduction ratios > 1.14 .

Furthermore, the DMFR was better in responders as determined by $\Delta\text{SUV}_{\text{mean}}$ ($n = 12$, 57.1%) than in non-responders ($n = 9$, 42.9%); the 1-year DMFRs were 83.3% vs. 31.1%, respectively ($p = 0.011$, Fig 3B). However, loco-regional control was not significantly different between the 2 groups; the 1-year LRFs were 90.9% and 63.5%, respectively ($p = 0.226$, Fig. 3A).

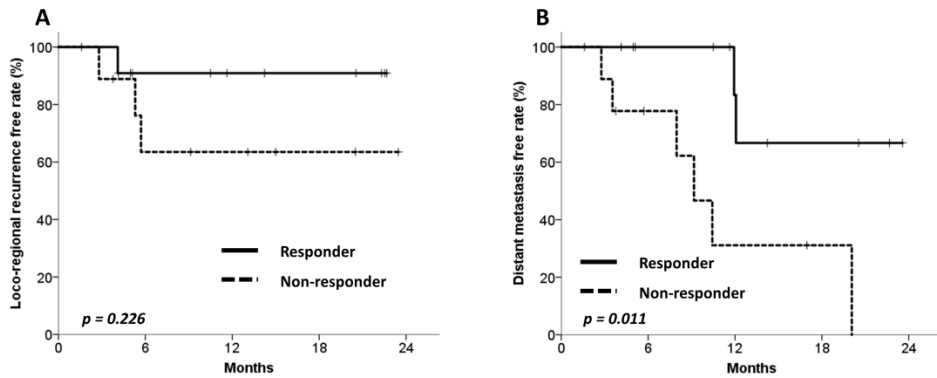

Figure 3. Loco-regional recurrence-free rate (A) and distant metastasis-free rate (B) of patients according to the mean standardized uptake value (SUV_{mean}) reduction rate. Responders were patients with SUV_{mean} reduction rates $>35\%$, while non-responders were patients with SUV_{mean} reduction rates $\leq 35\%$.

Based on the ΔMTV criteria, good responders ($n = 16, 76.2\%$) showed longer PFS than non-responders ($n = 5, 23.8\%$), with 1-year PFS rates of 34.6% and 0%, respectively ($p < 0.001$, Fig. 4A). The ΔMTV -based response criteria also exhibited borderline significance for OS, as the 1-year OS rates were 85.7% and 60.0%, respectively ($p = 0.051$, Fig. 4B). On the other hand, there were no significant differences in OS and PFS between good responders and non-responders based on the ΔSUV_{mean} criteria (Fig. 5).

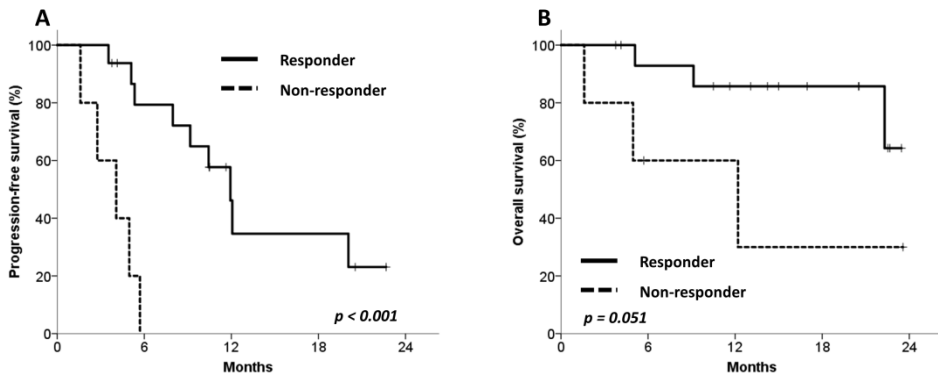

Figure 4. Progression-free survival (A) and overall survival (B) of patients according to the metabolic tumor volume (MTV) reduction ratio (mid-treatment MTV-to-pretreatment MTV). Responders were patients with MTV reduction ratios ≤ 1.14 , while non-responders were patients with MTV reduction ratios > 1.14 .

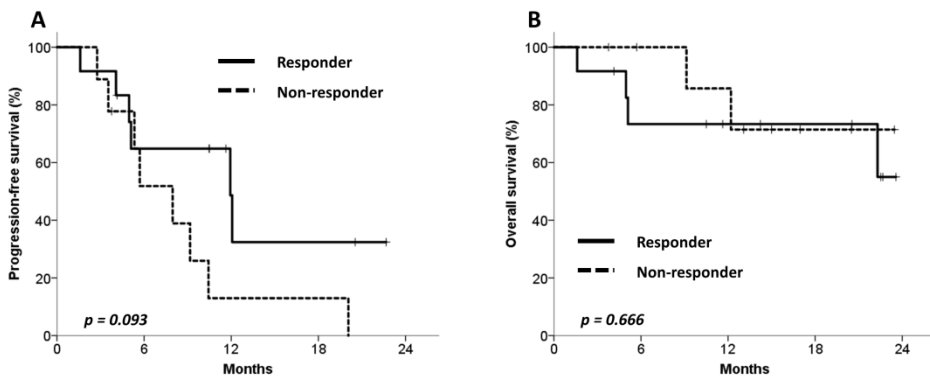

Figure 5. Progression-free survival (A) and overall survival (B) of patients according to the mean standardized uptake value (SUV_{mean}) reduction rate. Responders were patients with SUV_{mean} reduction rates $> 35\%$, while non-responders were patients with SUV_{mean} reduction rates $\leq 35\%$.

6. Diagnostic tests

The diagnostic test results are summarized in Table 4. Using the calculated

threshold of 1.14, the Δ MTV yielded a sensitivity of 60%, specificity of 94%, accuracy of 86%, PPV of 75%, and NPV of 88% for predicting locoregional recurrence. Furthermore, the Δ SUV_{mean} yielded a sensitivity of 67%, specificity of 83%, accuracy of 76%, PPV of 75%, and NPV of 77% for predicting distant metastasis when the calculated threshold of -35% was used.

Table 4. Diagnostic tests for metabolic response criteria based on MTV and SUV_{mean}

| | Value (%) | 95% CI (%) |
|--|------------------|-------------------|
| MTV - Locoregional recurrence | | |
| Pretest probability | 23.8 | 5.5 - 42.0 |
| Sensitivity | 60.0 | 17.1 - 102.9 |
| Specificity | 93.8 | 81.9 - 105.6 |
| Diagnostic Accuracy | 85.7 | 70.8 - 100.7 |
| Positive Predictive Value | 75.0 | 32.6 - 117.4 |
| Negative Predictive Value | 88.2 | 72.9 - 103.6 |
| SUV_{mean} - Distant metastasis | | |
| Pretest probability | 42.9 | 21.7 - 64.0 |
| Sensitivity | 66.7 | 35.9 - 97.5 |
| Specificity | 83.3 | 62.3 - 104.4 |
| Diagnostic Accuracy | 76.2 | 58.0 - 94.4 |
| Positive Predictive Value | 75.0 | 45.0 - 105.0 |
| Negative Predictive Value | 76.9 | 54.0 - 99.8 |

Abbreviations: CI, confidence interval; MTV, metabolic tumor volume; SUV_{mean}, mean standardized uptake value

IV. DISCUSSION

We examined the value of using ^{18}F -FDG PET metrics before and during chemoradiation in predicting responses to treatment in patients with esophageal cancer. We calculated an optimal cut-off value for ΔMTV (a ratio of 1.14), which was predictive of locoregional recurrence, as well as a cut-off value for the $\Delta\text{SUV}_{\text{mean}}$ (a 35% reduction), which was predictive of distant metastasis. These factors showed satisfactory abilities to predict inadequate responses to RT, indicating that the ΔMTV and $\Delta\text{SUV}_{\text{mean}}$ could be useful for identifying responders.

An accurate prediction of pathologic responses is critical, since patients with poor responses are exposed to unnecessary treatment-related toxicities [13,14]. Therefore, the predictive value of ^{18}F -FDG PET/CT response during treatment has been widely accepted in preoperative chemotherapy for patients with esophageal cancer [9,15,16]. Previous studies of ^{18}F -FDG PET/CT before and after induction chemotherapy found a significant association between early metabolic response and histopathologic tumor regression [17].

The early response appears to be an indicator of tumor biology and a predictor of the likelihood of treatment failure. As such, early response evaluation can help identify patients who are eligible for treatment intensification or modification, and thus reduce treatment failures in poor responders (the so-called ^{18}F -FDG PET/CT guided treatment algorithm). The MUNICON trial prospectively confirmed the feasibility and usefulness of the ^{18}F -FDG PET/CT guided treatment algorithm in patients with esophageal cancer. Poor metabolic responders halted chemotherapy

and switched to immediate surgery; such early termination of chemotherapy based on metabolic responses did not negatively affect clinical outcome [9,16].

Tumor stage, nodal stage, and patient characteristics (including morphological information evaluated using esophagoscopy and CT) were not statistically significant prognostic factors on multivariate analysis in our study. Moreover, delineated gross tumor volume based on simulation CT was not associated with locoregional recurrence or distant metastasis. On the other hand, the changes in SUV or MTV in the primary tumor, as measured by ^{18}F -FDG PET/CT, are dependent on glucose metabolism and reflect the changes in tissue viability in response to chemoradiation. Notably, other series that examined the prognostic value of PET metrics in patients receiving chemotherapy and/or RT for esophageal cancer identified different prognostic metrics, ranging from SUV_{max} [18,19] to a percentage decrease in TLG [20], the percentage decrease in MTV and TLG [21,22], and the PET2-based MTV and TLG values themselves [23]. However, there remain statistical concerns such as multiple comparisons and selective reporting of endpoints, because most of these studies were retrospective and examined multiple outcomes. In our series, a small decrease in PET2 MTV was associated with local recurrence, suggesting that this parameter may help select patients that would benefit from further local RT dose escalation. Another promising direction is to consider early switching of systemic chemotherapy in patients with a small decrease in SUV_{mean} . Further investigations are required to determine whether additional salvage strategies, such as early switching of concurrent systemic therapy,

would be beneficial.

Decrease in MTV represents volumetric changes in the size of high metabolic tumor cells. Thus, it is reasonable to suspect that Δ MTV after local RT might be a more effective predictor than SUV values in regards to locoregional recurrence [24,25]. The SUV_{mean} is the SUV value based on MTV. The SUV_{mean} represents the enhanced tapping of ^{18}F -FDG into the tumor cells due to biological mechanisms, tumor aggressiveness, and hypoxia [26,27]. Therefore it provides information of inherent tumor characteristics which suggests a tendency to distant metastasis. In addition, it is well known that the accuracy of CT for assessment of extent in esophageal cancer is limited in the determination of T status [28, 29]. It is the reason why delineated gross tumor volume does not have its prognostication ability.

Our study had several limitations. First, the results should be interpreted with caution because this was a retrospective analysis. Second, ours was a single-center study, which would therefore carry inherent biases. However, our analysis was strengthened by including all possible PET metrics in our diagnostic tests using modern ^{18}F -FDG PET/CT techniques and imaging analyses. Other limiting factors include possible inflammatory changes caused by irradiation, which may mimic changes in tumor glucose metabolism associated with treatment effect [30]. However, all patients underwent mid-RT ^{18}F -FDG PET/CT two weeks after the initiation of treatment which could minimize the possible inflammatory effects when interpreting tumor metabolism. Additionally, because of the partial-volume

effect, tumor shrinkage upon initiation of treatment may lead to underestimation of the FDG uptake observed on mid-treatment ^{18}F -FDG PET/CT scans, and a consequent overestimation of the change of parameters such as the SUV [2]. While measuring changes in FDG uptake is a widely adopted parameter that reflects the proportion of viable tumor cells, the development of additional new tracers specific to apoptosis and proliferation may help provide an even more accurate prediction of RT response.

V. CONCLUSION

We found the correlation between decrease in MTV with locoregional recurrence and decrease in SUV_{mean} with distant metastasis, respectively, in esophageal cancer patients treated with chemoradiation therapy. The optimal management of patients with poor responses identified on mid-RT ^{18}F -FDG PET/CT remains to be determined. Furthermore, a prospective study to confirm the efficacy of ^{18}F -FDG PET/CT-guided algorithms in patients with esophageal cancer is warranted.

ABSTRACT (IN KOREAN)

식도암 환자에서 방사선 치료 중 ^{18}F -FDG PET/CT의 임상적 의의

<지도교수 이 창 결>

연세대학교 대학원 의학과

김 나 리

목적: 식도암 환자에 있어서 방사선치료를 하는 동안 ^{18}F -fluorodeoxyglucose (^{18}F -FDG) 양전자 방출 단층 촬영기를 이용한 조기 대사 반응이 예후를 예측하는데 도움이 되는지 알아보하고자 하였다.

대상 및 방법: 식도암에 대한 방사선치료를 받은 환자 중 치료 중 ^{18}F -FDG 양전자 방출 단층 촬영을 시행한 21명의 환자를 대상으로 하였다. 대상 환자들은 방사선치료 11회 진행 이후 두번째 ^{18}F -FDG 양전자 방출 단층 촬영을 시행 하였다. 치료 전과 치료 중 양전자 방출 단층 촬영에 대해 PET Edge 방법을 이용하여 원하는 부분을 계산하였다. 최대 그리고 평균 표준화섭취계수 (SUV_{max} , SUV_{mean}), 대사활성종양부피 (MTV), 그리고 total lesion glycolysis (TLG) 를 산출하였다.

결과: 추적 관찰 기간 중간값은 13 개월이었고, 1년 생존율, 무병생존율은 각각 79.0%, 34.4% 였다. 총 14명의 환자가 국소재발을 경험하였고, 8명의 환자에게 원격전이가 발생하였다. 1년 국소 제어율은 76.9% 였고, 1년 원격 무전이 발생율은 60.6%

였다. 상대적인 MTV 감소량은 국소 재발율과 관계가 있었다 ($p=0.03$). 반대로, SUV_{mean} 의 감소량은 원격전이와 관계가 있었다 ($p=0.02$). MTV 감소량에 대한 기준비를 1.14로 볼 때, 국소 재발율을 예측하는 데에 있어 민감도는 60%, 특이도는 94%, 그리고 정확도는 86% 의 능력을 보였다. 추가적으로, SUV_{mean} 의 감소량에 대한 기준 값을 35% 로 볼 때, 이는 원격전이를 민감도 67%, 특이도 83%, 그리고 정확도 76% 로 예측하는 능력을 보였다.

결론: 식도암 환자의 방사선치료 중 시행한 양전자단층촬영을 바탕으로 종양의 대사 변화를 검사하는 것은 치료반응, 재발 그리고 전이에 대한 정보를 제공할 수 있을 것으로 보인다.

핵심 되는 말: 방사선치료, 식도암, 대사 반응, 예후, ^{18}F -FDG
