

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

Estimating COVID-19 Infection and Severity Risks in Patients with Chronic Rhinosinusitis: A Korean Nationwide Cohort Study

Seung Won Lee, MD, PhD^{a,*}, So Young Kim, MD^{b,*}, Sung Yong Moon, BS^a, Jee Myung Yang, MD, PhD^c, Eun Kyo Ha, MD^d, Hye Mi Jee, MD, PhD^e, Jae Il Shin, MD, PhD^f, Seong Ho Cho, MD^g, Dong Keon Yon, MD, FACAAl^h, and Dong In Suh, MD, PhD^h *Seoul and Seongnam, South Korea; and Tampa, Fla*

What is already known about this topic? Chronic rhinosinusitis (CRS) is one of the most common upper airway inflammatory diseases and may be associated with epithelial barrier dysfunction, bacterial colonization, exaggerated immune response, and specific antibody deficiency. Basic studies suggest that CRS may increase coronavirus disease susceptibility or severity; however, the potential association of CRS with coronavirus disease 2019 (COVID-19) susceptibility or severity has not been demonstrated.

What does this article add to our knowledge? In our large-scale, population-based nationwide cohort in South Korea, CRS was associated with an increased risk for severe acute respiratory syndrome coronavirus 2 infection and severe COVID-19. In particular, among patients with CRS, prior intranasal corticosteroid use, the absence of nasal polyps, or nonatopic type were associated with a greater risk for severe acute respiratory syndrome coronavirus 2 infection, and severe COVID-19 outcomes.

How does this study impact current management guidelines? Taken together, our findings suggest that clinicians should be cautious in assessing the prognosis and determining care for patients with CRS amid the COVID-19 pandemic.

BACKGROUND: Basic studies suggest that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection can affect chronic rhinosinusitis (CRS), but there is unclear real-world evidence regarding the association of underlying CRS with the risk for SARS-CoV-2 infection and severe coronavirus disease 19 (COVID-19). **OBJECTIVE:** We aimed to determine whether CRS is associated with increased risk for SARS-CoV-2 infection and severe COVID-19.

METHODS: Altogether, 219,959 adult patients who tested for SARS-CoV-2 in South Korea from January 1 to May 15, 2020 (excluding self-referral) were identified in this nested case-control study with propensity score matching. Data on

SARS-CoV-2 test results and COVID-19 worsened outcomes (ie, the need for oxygen therapy, intensive care, or mechanical ventilation, and death) were obtained from the Health Insurance Review and Assessment Service of Korea.

RESULTS: In this matched cohort, 380 of 12,217 patients with CRS (3.1%) tested positive for SARS-CoV-2 infection, compared with 310 patients without CRS (2.5%; adjusted odds ratio = 1.22; 95% confidence interval, 1.04-1.42). Moreover, 60 of 286 COVID-19 patients with CRS (21.0%) had severe COVID-19 outcomes, compared with 38 without CRS (13.3%; adjusted odds ratio = 1.71; 95% confidence interval, 1.09-2.71). Subgroup analysis identified that CRS patients with an absence

INTRODUCTION

A global pandemic of coronavirus disease 2019 (COVID-19) began in December 2019, when the pathogen of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was first identified in Wuhan, China.¹⁻³ Severe acute respiratory syndrome coronavirus 2 invades host cells by binding its spike proteins to receptor-angiotensin converting enzyme II (ACE2)³ and by their priming and fusion with the cell membrane by host transmembrane serine protease 2 (TMPRSS2).⁴ In addition to the different expression levels or affinities of viral entry factors, host immunity functions could influence the infectivity or severity of COVID-19.⁴ Thus, asthma,² allergic rhinitis,² chronic obstructive pulmonary disease,^{5,6} and immune-compromised status⁷ have been reported to be potentially associated with increased susceptibility to or severity of COVID-19.

In addition to the lower airway, COVID-19 has been suggested to have a high impact on the upper airway.⁸ The viral load of SARS-CoV-2 was found to be higher in nasal swabs than in throat swabs in both symptomatic and asymptomatic patients.⁹ Furthermore, in healthy human tissues, higher expression levels of viral entry-associated genes ACE2 and TMPRSS2 were observed in nasal epithelial cells than in lower respiratory tract, corneal, and intestinal epithelial cells.^{10,11} In the respiratory tract, a gradient was found in ACE2 expression and SARS-CoV-2 infection levels from the nose to the distal pulmonary epithelium, which suggests that SARS-CoV-2 affinity to the respiratory epithelium combined with inhalation-related viral spreading could explain the pathogenesis of COVID-19.¹²

Chronic rhinosinusitis (CRS) is one of the most common upper airway inflammatory diseases and could be associated with epithelial barrier dysfunction, bacterial colonization, exaggerated immune response, and specific antibody deficiency.^{13,14} Owing to the upper airway inflammatory condition, epithelial barrier dysfunction, and high expression levels of viral entry genes, CRS may increase COVID-19 susceptibility or severity. Previous preliminary studies were equivocal,^{11,15} and the potential association of CRS with COVID-19 susceptibility or severity has not yet been clarified.

In this nested case-control study in a Korean nationwide cohort, we investigated the potential association of CRS with SARS-CoV-2 infection (SARS-CoV-2 positive test result) and COVID-19 severity (COVID-19 worsened outcomes; including oxygen therapy, intensive care unit admission, use of mechanical ventilation, or death).

METHODS

The data were obtained from the Korea Centers for Disease Control and Prevention (KCDC), the Health Insurance Review and Assessment Service of Korea, and the Ministry of Health and Welfare in South Korea. As previously described, the nationwide cohort^{2,3,16,17} had the following characteristics: (1) the Korean government provided a complimentary medical service for all COVID-19 patients; (2) the data consisted of health insurance claims over the previous 3.5 years (January 1, 2017 to May 15, 2020) of all patients who were tested for SARS-CoV-2 through KCDC or medical referrals (excluding self-referral); and (3) this health insurance claim-based cohort was kept anonymous to guarantee the confidentiality of COVID-19 infection status.

The study protocol was approved by the Institutional Review Board of Sejong University (SJU-HR-E-2020-003). The requirement for written consent was waived by the ethics committee because of urgent medical needs to be met amid the COVID-19 pandemic.

Study population

All adults (aged ≥ 20 years) who were tested for SARS-CoV-2 in South Korea from January 1, 2020 to May 15, 2020 (total $n = 219,959$, excluding self-referral) were enrolled. The observation period was from January 1, 2017 to May 15, 2020, and the individual index date was defined as the date of the first SARS-CoV-2 test. The medical history was defined using International Classification of Disease 10th revision (ICD-10) codes and at least two inpatient or outpatient claims within 1 year, as previously described.^{2,3} The Charlson comorbidity index score was calculated, and the region of residence was classified as rural or urban, as previously described.^{2,3,18,19} The use of medications was defined based on medications taken within 6 months before the individual index date.^{2,3}

Exposure

We defined CRS using the ICD-10 code (J32) with at least two claims within 1 year and the use of head and neck computed tomography. We defined CRS with nasal polyp (CRSwNP) using ICD-10 codes J32 plus J33, and CRS without nasal polyp (CRSsNP) using ICD-10 code J32 alone.²⁰ Atopic CRS was defined as CRS with another allergic disease (asthma, atopic dermatitis, or allergic rhinitis), and nonatopic CRS as CRS with no other allergic disease.^{2,21,22}

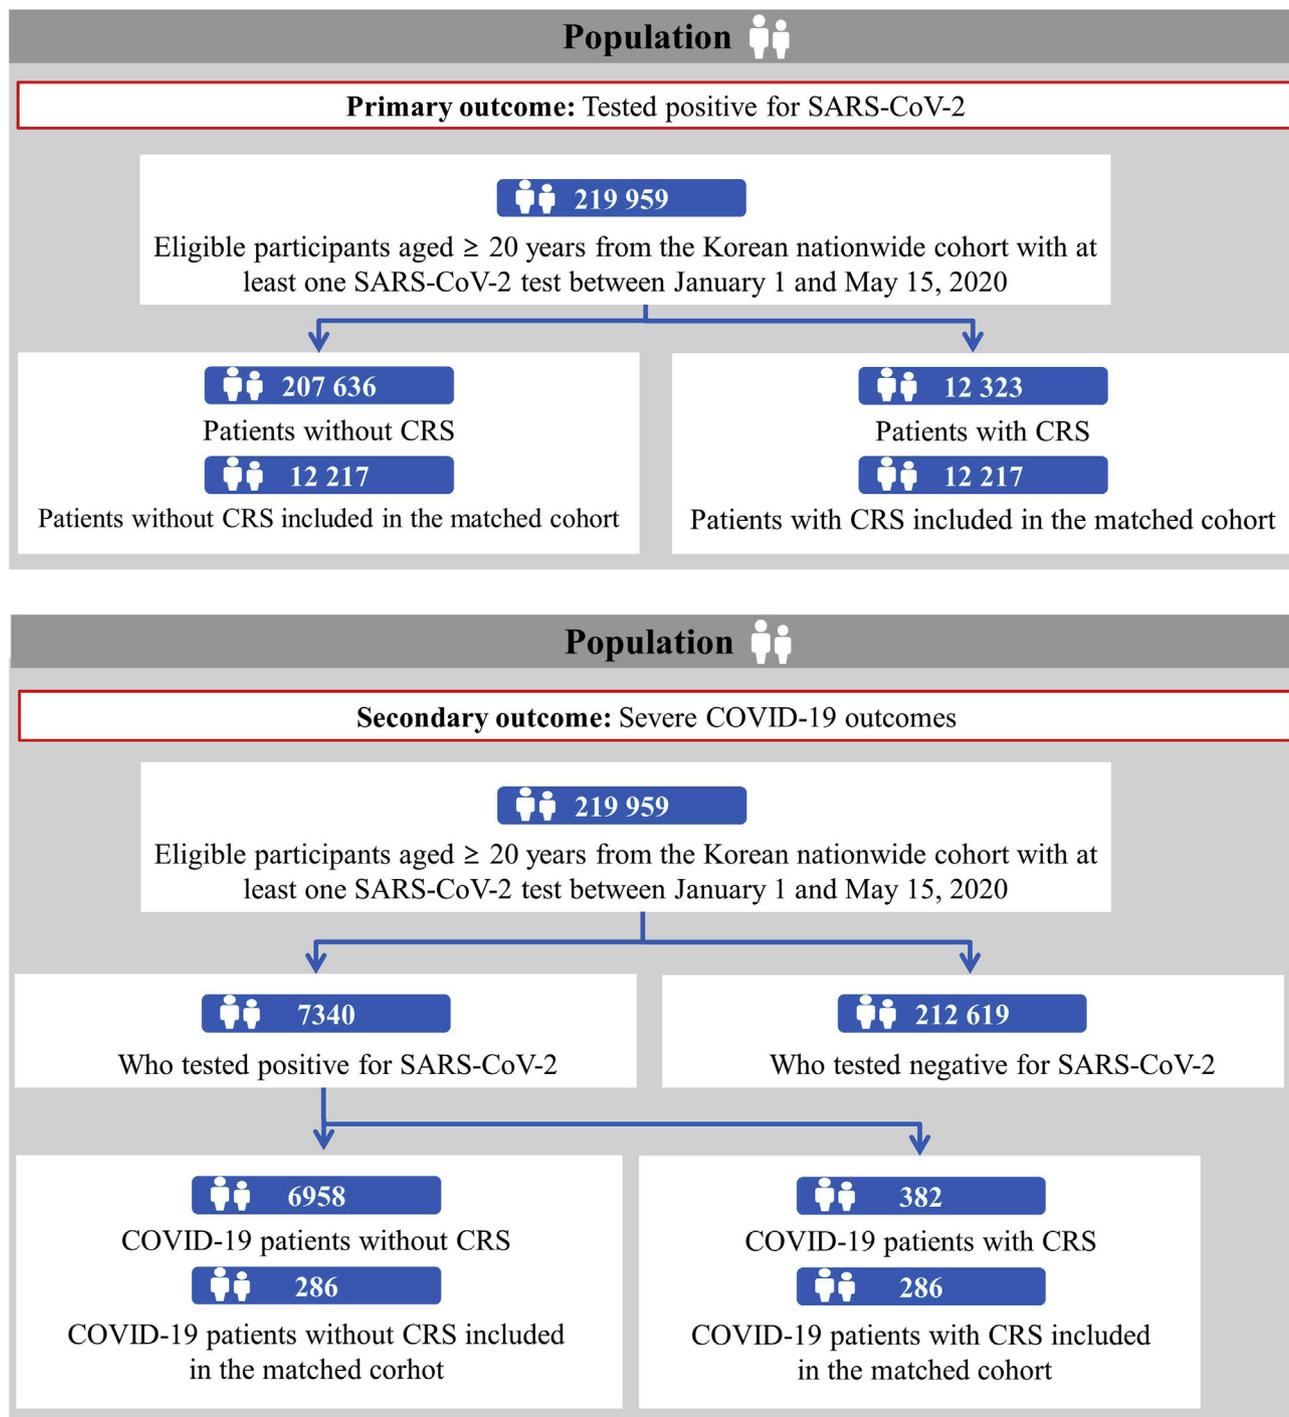

FIGURE 1. Participant flowchart. COVID-19, coronavirus disease; CRS, chronic rhinosinusitis; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

Outcomes

The primary outcome was a positive SARS-CoV-2 test result (laboratory-confirmed COVID-19) from real-time reverse transcription-polymerase chain reaction assays of pharyngeal or nasal swabs performed according to the guidelines of the World Health Organization and KCDC.¹⁻³ Secondary outcomes were severe COVID-19 outcomes, including the requirement of oxygen therapy,

intensive care unit admission, use of mechanical ventilation, or death.³

Statistical analysis

In the nationwide cohort, preexisting CRS was defined as the exposure; a positive SARS-CoV-2 test result or severe COVID-19 outcomes were defined as the outcomes. We performed the

CRS, chronic rhinosinusitis.

exposure propensity score matching method. Therefore, we used a 1:1 ratio greedy nearest-neighbor matching on the logit of the propensity score with the calipers less than 0.001 to balance the covariates of age (continuous); sex; region of residence (urban and rural); a history of diabetes mellitus, cardiovascular disease, cerebrovascular disease, chronic obstructive pulmonary disease, hypertension, or chronic kidney disease; Charlson comorbidity index (0, 1, and ≥2); and use of medication (aspirin, metformin, or statin). We used two rounds of propensity score matching between patients without CRS versus patients with CRS: (1) among all patients who were tested for SARS-CoV-2 (n = 219,959) and (2) among patients with COVID-19 (n = 7340). We confirmed the adequacy of the propensity score matching as assessed by the propensity score densities (see [Figures E1 and E2](#) in this article's Online Repository at www.jaci-inpractice.org) and standardized mean differences (SMDs).^{2,21-23}

Main analysis

Data were analyzed using Firth's bias-reduced logistic regression to reduce the small sample bias and adjusted odds ratios (aORs) with 95% confidence intervals (CIs) in each matched cohort, after adjusting for age; sex; region of residence; a history of diabetes mellitus, cardiovascular disease, cerebrovascular disease, chronic obstructive pulmonary disease, hypertension, chronic kidney disease, or nasal polyp; Charlson comorbidity index; and the use of medication (systemic or intranasal corticosteroids, aspirin, metformin, or

statin). We performed several sensitivity analyses, applying stratification by nasal polyp (CRSwNP or CRSsNP), atopic phenotype (atopic CRS or nonatopic CRS), and prior intranasal corticosteroid use (CRS treated with or without intranasal corticosteroids). Statistical analyses were performed using SAS software (version 9.4, SAS Institute Inc, Cary, NC) and R software (version 3.1.1, R Foundation, Vienna, Austria).¹⁷ A two-tailed *P* value less than .05 was considered statistically significant.

RESULTS

Full unmatched cohort

In the entire study population (n = 219,959), we identified 207,636 patients without CRS (94.4%) and 12,323 with CRS (5.6%) ([Figure 1](#)). Among 7340 patients with laboratory-confirmed COVID-19, there were 6958 without CRS (94.8%) and 382 with CRS (5.2%). The positivity rate of the SARS-CoV-2 test was 3.3% (7340 of 219,959) in the entire study population, 2.3% in patients without CRS (6958 of 207,636), and 3.1% in patients with CRS (382 of 12,323).

Matched cohort

[Table I](#) reports the baseline characteristics of all patients tested for SARS-CoV-2 and all COVID-19 patients stratified by CRS. In the matched cohort (n = 24,434), baseline covariates were balanced between patients with and without CRS ([Table II](#) and [Figure 2](#)) (all SMDs <0.05). Patients with CRS had a 22%

CRS, chronic rhinosinusitis; SMD, standardized mean difference; OR, odds ratio.

Bolded data indicate significant differences in the regression model ($P < .05$).

*An SMD less than 0.1 indicates no major imbalance. All SMD values were less than 0.05 in the propensity score–matched cohort.

†Minimally adjusted for age and sex.

‡Fully adjusted for age; sex; region of residence; history of diabetes mellitus, cardiovascular disease, cerebrovascular disease, chronic obstructive pulmonary disease, hypertension, chronic kidney disease, or nasal polyp; Charlson comorbidity index; and previous use of medication (systemic or intranasal corticosteroids, aspirin, metformin, or statin).

greater risk for SARS-CoV-2 infection after fully adjusting for confounding factors compared with patients without CRS (3.1% vs 2.5%; fully aOR = 1.22; 95% CI, 1.04-1.42). The stratification analysis found that patients with CRS had a 61% greater risk for severe COVID-19 compared with those without CRS (see Table E1 in this article's Online Repository at www.jaci-inpractice.org) (0.7% vs 0.4%; fully aOR = 1.61; 95% CI, 1.12-2.29).

Next, patients with confirmed COVID-19 were matched for all baseline covariates between those with and without CRS (Table III and Figure 2) (all SMDs <0.1), except for a history of chronic obstructive pulmonary disease (SMD = 0.100). Patients with CRS had a 71% greater risk for severe COVID-19 outcomes after fully adjusting for confounding factors compared with patients without CRS (21.0% vs 13.3%; fully aOR = 1.09; 95% CI, 1.09-2.71).

Propensity score-matched subgroup analysis

Table IV reports the subgroup analysis of the effect of nasal polyps, intranasal corticosteroid use, and atopic status. Patients with CRSwNP did not experience a greater risk for SARS-CoV-2 infection (fully aOR = 1.01; 95% CI, 0.67-1.51) and severe COVID-19 outcomes (fully aOR = 1.34; 95% CI, 0.40-4.20)

compared with patients without CRS. Patients with CRSsNP had a greater risk for SARS-CoV-2 infection (fully aOR = 1.24; 95% CI, 1.06-1.44) and severe COVID-19 outcomes (fully aOR = 1.75; 95% CI, 1.10-2.75) compared with patients without CRS.

Chronic rhinosinusitis patients treated with intranasal corticosteroids had a greater risk for SARS-CoV2 infection (aOR = 1.32; 95% CI 1.03-1.73) and severe COVID-19 outcomes (fully aOR = 2.24; 95% CI, 1.16-4.20) compared with CRS patients treated without intranasal corticosteroids (SARS-CoV-2 infection fully aOR = 1.19; 95% CI, 1.01-1.40; severe COVID-19 outcomes fully aOR = 1.55; 95% CI, 0.95-2.50). Patients with nonatopic CRS had a greater risk for SARS-CoV2 infection (aOR = 1.34; 95% CI 1.05-1.70) and severe COVID-19 outcomes (fully aOR = 2.27; 95% CI, 1.14-4.36) compared with patients with atopic CRS (SARS-CoV-2 infection fully aOR = 1.20; 95% CI, 1.00-1.41; $P < .05$; severe COVID-19 outcomes fully aOR = 1.56; 95% CI, 0.97-2.51).

DISCUSSION

We investigated the risk for COVID-19 susceptibility and severity in patients with CRS in a large-scale, population-based

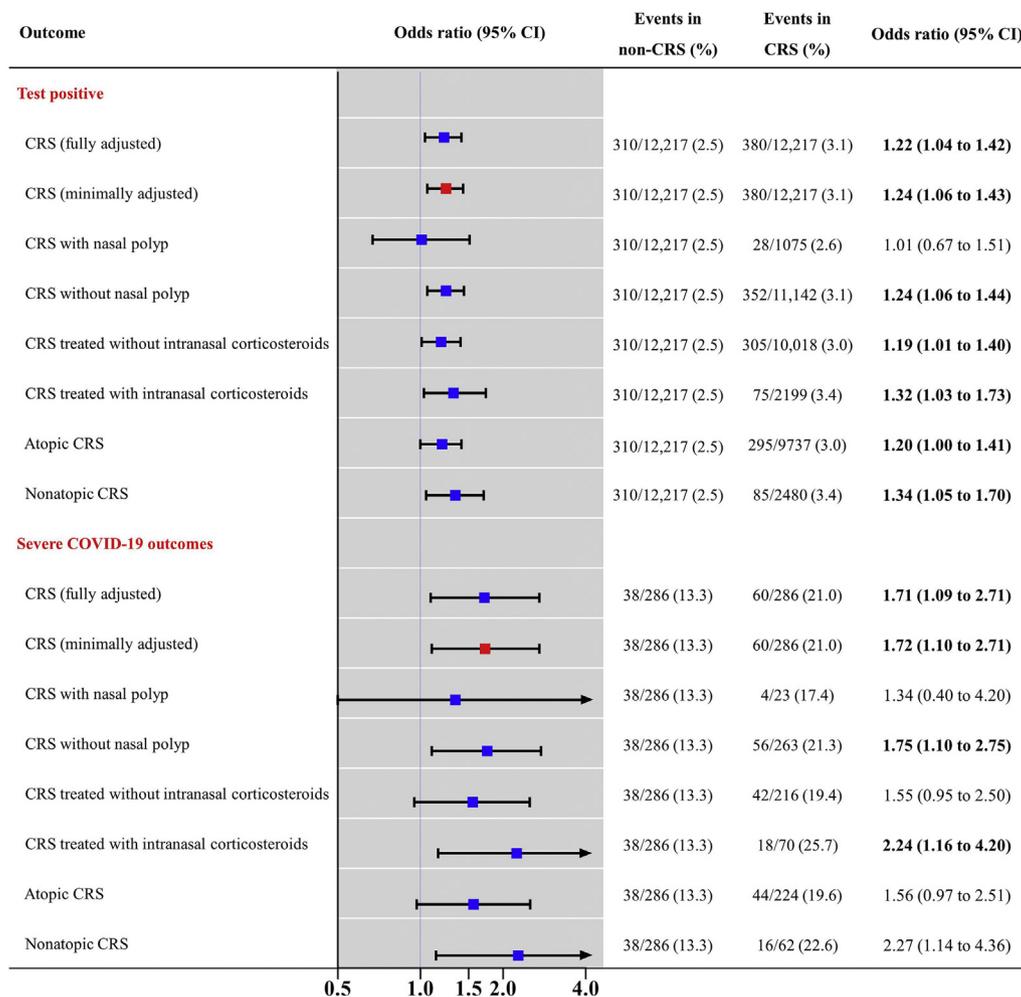

FIGURE 2. Propensity score-matched association of chronic rhinosinusitis (CRS) with coronavirus disease 19 (COVID-19) susceptibility and severity. Firth’s bias-reduced logistic regression analysis ORs with 95% CIs are presented. Severe COVID-19 outcomes were the need for oxygen therapy, admission to the intensive care unit, invasive ventilation, or death. The x-axis indicates a log-scale; red dots indicate minimal adjustment and blue dots indicate full adjustment. *CI*, confidence interval; *COPD*, chronic obstructive pulmonary disease; *OR*, odds ratio; *SARS-CoV-2*, severe acute respiratory syndrome coronavirus 2.

nationwide cohort in South Korea (n = 219,959). Patients with CRS had an increased risk for COVID-19 susceptibility and severity compared with people without CRS (Figure 3). In particular, CRSsNP, CRS treated with intranasal corticosteroids, and nonatopic CRS conferred a greater risk for SARS-CoV-2 infection and COVID-19 severity, although the event numbers were small.

Possible explanations of main results

To the authors’ knowledge, this is the first real-world study to investigate potential associations between a diagnosis of CRS and the risks for SARS-CoV-2 infection and severe COVID-19. Previously, CRS was reported to increase the risks for pneumonia, sepsis, and mortality.^{24,25} Those studies suggested that CRS could provide bacterial or viral reservoirs and reduce nitric oxide production in the sinus, implying impaired local host defense and increased susceptibility to secondary infection.^{24,25} It is known that CRS is associated with immune dysfunction, such as epithelial

barrier dysfunction^{13,26} and specific antibody deficiency,¹⁴ which may contribute to increased COVID-19 infectivity and severity.

The increased infectivity to SARS-CoV-2 and severity of COVID-19 observed in patients with CRS might be explained by several plausible mechanisms. First, the impairment of sinonasal epithelial barrier functions could increase the exposure of patients with CRS to viral pathogens and their invasion. The mucociliary clearance of viral pathogens might be impeded in CRS patients. Sinonasal epithelial cells in CRS patients have been shown to exhibit morphologic and functional changes in basal cell proliferation, goblet cell hyperplasia, and the loss of ciliated cells.²⁷ Second, patients whose CRS is caused by a viral infection may be more susceptible to viral coinfection, in particular with SARS-CoV-2. In a previous study,²⁸ CRS patients showed a 2.9 times higher rate of viral infection in nasal lavage fluids and nasal mucosa compared with patients without CRS, and approximately 21.6% of patients with CRS showed coronavirus infection.

TABLE III. One-to-one propensity score–matched baseline characteristics and adjusted ORs (95% confidence intervals) for association of severe coronavirus disease 2019 with CRS among patients with laboratory-confirmed coronavirus disease 2019

COPD, chronic obstructive pulmonary disease; CRS, chronic rhinosinusitis; OR, odds ratio; SMD, standardized mean difference.

Bolded data indicate significant differences in the regression model ($P < .05$).

*An SMD less than 0.1 indicates no major imbalance. All SMD values were less than 0.1 in the propensity score–matched cohort, except a history of COPD.

†Severe outcomes of coronavirus disease 2019 were the need for oxygen therapy, admission to the intensive care unit, invasive ventilation, or death.

‡Minimally adjusted for age and sex.

§Fully adjusted for age; sex; region of residence; history of diabetes mellitus, cardiovascular disease, cerebrovascular disease, COPD, hypertension, chronic kidney disease, or nasal polyp; Charlson comorbidity index; and previous use of medication (systemic or intranasal corticosteroids, aspirin, metformin, or statin).

Third, the high expression levels of ACE2 and TMPRSS2 in the sinonasal cavity might have a role in the viral entry and transmission of SARS-CoV-2.^{10,12,29} The sinonasal cavity and the nasal epithelium are two regions with the highest ACE2 protein expression within the human respiratory tract.^{10,12,29} Therefore, viral retention in the sinonasal cavity caused by CRS could accelerate the intracellular entry of SARS-CoV-2 by binding the viral receptor to ACE2 and its cofactor to TMPRSS2. Fourth, local inflammatory responses in patients with CRS could modulate susceptibility to COVID-19. Impaired antiviral innate immune responses in sinonasal epithelial cells occur in CRS patients during inflammation.³⁰ Sinonasal inflammatory responses can increase the expression of proinflammatory cytokines such as interferon (IFN) in CRS patients,³¹ which in turn can upregulate the expression of ACE2.³² Thus, local inflammation with increased IFN in CRS patients could induce ACE2-mediated SARS-CoV2 infection.³² Consistent with local inflammation in CRS that possibly contributes to the development of COVID-19, an inhibitor of interleukin-4 and interleukin-13 (dupilumab) has been reported potentially to alleviate the severity of COVID-19.^{33,34} Altogether, the combined effects of impaired barrier functions, viral coinfection, increased expression of viral entry-associated factors,

and local inflammatory response might contribute to the increased susceptibility to SARS-CoV-2 infection and severity of COVID-19 observed in CRS patients.

In our subgroup analysis, patients with CRSsNP or nonatopic CRS showed a higher rate of infection with SARS-CoV-2 and increased severity of COVID-19 compared with patients with CRSwNP or atopic CRS. Patients with CRSwNP or nonatopic CRS may prominently exhibit type 2 immune responses with downregulation of IFNs, which in turn might downregulate ACE2 expression.⁸ An *in vivo* study of asthmatic rats with type 2 immune responses, which were given an ACE2 activator, demonstrated decreased expression of ACE2 together with the alleviation of altered airway responsiveness, eosinophilia, and inflammatory changes.^{35,36} Consistent with this observation, our previous real-world study² suggested a greater risk for a positive SARS-CoV-2 test and severe COVID-19 in patients with nonallergic asthma compared with patients with allergic asthma. Furthermore, a recent study³⁷ found that asthmatic patients with preexisting eosinophilia had a protective association from COVID-19—associated admission and mortality. Altogether, these studies suggest that a prominent type 2 immune response caused by nasal polyps may contribute to lower SARS-CoV-2 infectivity and COVID-19 severity compared with CRSsNP.

TABLE IV. Propensity score–matched subgroup analyses for association of risk for positive SARS-CoV-2 test result with CRS by nasal polyp, prior intranasal corticosteroid use, and atopic phenotype among all patients who underwent SARS-CoV-2 testing, and for association of risk for COVID-19 worse outcomes with CRS by nasal polyp, prior intranasal corticosteroid use, and atopic phenotype among patients with laboratory-confirmed COVID-19

FIGURE 3. Graphical abstract. aOR, adjusted odds ratio; CI, confidence interval; COVID-19, coronavirus disease 19; CRS, chronic rhinosinusitis; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

Interestingly, we found that prior use of nasal corticosteroids increased the risk for SARS-CoV-2 infection and the severity of COVID-19. Recent *in vitro* and *in vivo* studies³⁸ suggest that

inhaled corticosteroids may have beneficial or detrimental contributions to the altered susceptibility or severity of COVID-19. Because it is difficult to distinguish between the direct effect of

using intranasal corticosteroids and more severe CRS requiring intranasal corticosteroids, the clinical significance of the current intranasal corticosteroid results is not clear.

Limitations and strengths

Several limitations should be considered when interpreting these results, mainly owing to a lack of sufficient information about the study population. In particular, CRS endotypes could not be differentiated because the current study used health insurance claims-based data with ICD-10 codes and lacked laboratory findings and biomarkers. Furthermore, the history of endoscopic sinus surgery was not considered. Because of the heterogeneous types, varying severity, and an inaccurate claims-based definition of CRS in this cohort, this study might have underestimated the relation between CRS and the infectivity of SARS-CoV-2 or severity of COVID-19. The classification of CRS patients according to the atopic status was based on the ICD-10 codes; thus, misdiagnosed cases or untreated cases may have been excluded in this study. Furthermore, ethnic differences in atopic CRS could explain the conflicting results regarding the association of atopic CRS with COVID-19.³⁹ The relatively small study population of atopic patients and that of patients with nasal polyps limited the statistical power in this study. Furthermore, although we adjusted for comorbidities, including chronic obstructive pulmonary disease, other confounding factors such as smoking could exist.⁴⁰ Second, CRS-related confounders might affect our main results. Although we used a large-scale nationwide cohort and a sophisticated matching technique to reduce bias, anosmia associated with CRS can cause more frequent SARS-CoV-2 testing, which may increase the selection bias.⁴¹ Also, CRS can cause sinonasal symptoms, which may make wearing masks less tolerable during the COVID-19 pandemic. Finally, the study population was limited to Koreans, and the association of CRS with the infectivity of SARS-CoV-2 or the severity of COVID-19 could reveal differences in other ethnic groups.⁴² In particular, type 2/atopic/eosinophilic nasal polyps are less common in Asians.³⁹ The infectivity or severity of COVID-19 in CRS may not show a significant difference in Western countries owing to this geographic and ethnic difference in CRS endotypes.

Despite these limitations, this large-scale, population-based, nationwide cohort study evaluated the potential relation between CRS and SARS-CoV-2 infection and COVID-19 severity. We used a large sample and representative population ($n = 219,959$), sophisticated statistical techniques to identify accurate predictors of an outcome (propensity score matching to reduce potential confounders and selection bias and Firth bias correction to decrease the small sample bias), and a strict CRS definition (ICD code claims supported by head and neck computed tomography). During the current COVID-19 pandemic, this study provides evidence that CRS is potentially associated with SARS-CoV-2 infectivity and COVID-19 severity.

Conclusions

Chronic rhinosinusitis was associated with an increased risk for SARS-CoV-2 infection and severe COVID-19 in this large-scale, population-based nationwide cohort in South Korea. In particular, CRSsNP, CRS treated with intranasal corticosteroids, or nonatopic CRS was associated with a greater risk for SARS-CoV-2 infection and severe COVID-19 outcomes. Taken together, our findings suggest that clinicians should be cautious

in assessing the prognosis and determining care for patients with CRS amid the COVID-19 pandemic.

Acknowledgments

The authors appreciate health care professionals dedicated to treating COVID-19 patients in Korea. The Ministry of Health and Welfare and the Health Insurance Review and Assessment Service of Korea is also acknowledged for sharing invaluable National Health Insurance claims data in a prompt manner.
