ACKNOWLEDGEMENTS

This work would not have been possible without teaching from Prof. Chong-Hyuk Choi who has given me consistent support and valuable advice from the residency to fellowship. I owe my utmost gratitude to Prof. Chong-Hyuk Choi. Also, I would like to express my deepest appreciation to Prof. Min Jung, who has always given me valuable advice and guidance to help me pull through this thesis. It has been an honor for me to wrap up my research under the direction of two of my mentors. In addition, I sincerely appreciate the thesis committee members: Prof. Kyung-Wook Nha, Prof. Sung-Rae Cho, and Prof. Young Han Lee. I would like to take this opportunity to thank my parents for being supportive and trustful throughout my life. Lastly, I give graceful and unending thanks to my wife and to my two daughters (Ah-Yoon and Yoon-Seo), for bringing sunshine to my life.

ABSTRACT

Three dimensional simulation study on the relationship between sagittal osteotomy inclination and posterior tibial slope changes in medial open wedge high tibial osteotomy

Jai Hyun Chung

Department of Medicine

The Graduate School, Yonsei University

(Directed by Professor Chong-Hyuk Choi)

In performing medial open-wedge high tibial osteotomy (MOWHTO), it is recommended that the posterior tibial slope should not be changed after surgery, but there is insufficient study on the effect of the osteotomy inclination angle in the sagittal plane on the posterior tibial slope. This study aimed to verify how anterior or posterior osteotomy inclination angle affects the tendency of change in the posterior tibial slope and to conduct quantitative analysis of the extent to which the posterior tibial slope changes according to the degree of the osteotomy inclination angle change in MOWHTO. Computed tomography images of 30 patients who underwent MOWHTO were collected. Three-dimensional models of preoperative original tibia were reconstructed, and virtual osteotomies were performed. The sagittal osteotomy inclination angles formed by the osteotomy line and medial tibial plateau line were classified as positive in case of anteriorly inclined osteotomy and negative

in case of posteriorly inclined osteotomy. Thirteen osteotomies were performed for each tibial model at intervals of 5° from -30° to 30° . The posterior tibial slope was assessed, and the proportional relationship between the sagittal osteotomy inclination angle and posterior tibial slope change was analyzed. The posterior tibial slope changed significantly after osteotomy ($P < 0.001$), except for the cases where the sagittal osteotomy inclination angle was 5° , 0° , and -5° . Anteriorly and posteriorly inclined osteotomy caused increase and decrease in the posterior tibial slope, respectively. As the inclination angle increased by 1° , the posterior tibial slope increased by 0.079° in anterior inclination osteotomy, while in posterior inclination osteotomy, as the inclination angle decreased by 1° , the posterior tibial slope decreased by 0.067° . The osteotomy inclination angle in the sagittal plane significantly affected the posterior tibial slope. When there was an inclination angle occurred between the osteotomy line and the medial tibial plateau line in the sagittal plane, the posterior tibial slope changed after MOWHTO. The posterior tibial slope tended to increase in anteriorly inclined osteotomy and decrease in posteriorly inclined osteotomy. The change in the posterior tibial slope was proportionally related to the absolute value of the osteotomy inclination angle.

I. INTRODUCTION

High tibial osteotomy is an effective procedure for medial compartment osteoarthritis of the knee with varus deformity in middle-aged patients.^{2,4,17} It reduces medial compartment pressure of the knee joint by realigning the mechanical axis of the lower extremity from medial to lateral compartment and redistributing the joint pressure, thereby reducing pain and improving function.^{8,24,26} A medial open-wedge high tibial osteotomy (MOWHTO) has become increasingly common in recent years due to several associated advantages, such as higher accuracy of correction,³⁹ lower risk of peroneal nerve complication compared with lateral closing wedge high tibial osteotomy.²⁴ The proximal tibial metaphyseal bone stock was also preserved without disruption of tibiofibular joint.³ This maintenance of the

proximal tibial configuration makes it easier to convert to total knee arthroplasty.^{11,15} Previous studies have shown that MOWHTO produces good clinical results including the low pain score and high activity levels with advanced Knee injury and Osteoarthritis Outcome Score (KOOS) and The Western Ontario and McMaster Universities Arthritis Index (WOMAC) scores.^{2,20,22,35} MOWHTO focuses primarily on realignment of the lower extremity in the coronal plane to relieve pain associated with osteoarthritis of the medial compartment of the knee.^{8,24} However, as the knee joint is a three-dimensional (3D) structure, when the osteotomy on the proximal tibia for the change of mechanical axis of the lower extremity (the line from the center of the femoral head to the center of the ankle joint²⁵) in the coronal plane is performed, the structural shape of the tibia in the sagittal plane also inevitably changes. Among the changes caused by the structural shape of the tibia in the sagittal plane, the change in the posterior tibial slope has significant clinical impact as it influences the biomechanics of the tibiofemoral joint.^{10,34} Increase in the posterior tibial slope can cause the tibia to shift anteriorly in relation to the femur and overload the anterior cruciate ligament and the patellofemoral joint.^{9,10,41} The posterior tibial slope has been reported to change after MOWHTO,³² and this change can be affected by various factors.^{7,23,33,37} The most common cause of change in the posterior tibial slope is an improper value of osteotomy opening gap ratio according to the difference between anterior and posterior osteotomy opening gaps.^{33,37} In addition to the opening gap ratio, it has been reported that the osteotomy inclination angle in the sagittal plane also affects the change in the posterior tibial slope. A previous clinical study reported that 87.1% of the osteotomy lines were inclined anteriorly in the sagittal plane, and anteriorly inclined osteotomy was positively correlated with the change in the posterior tibial slope.²³ Another clinical study⁷

demonstrated that even if the osteotomy opening gap ratio is preserved at an appropriate value during MOWHTO, the postoperative posterior tibial slope can change depending on the sagittal osteotomy inclination angle. The postoperative posterior tibial slope increased when the anterior part of the osteotomy line was inclined distally with respect to the line parallel to the medial tibial plateau line in the sagittal plane, and decreased when the anterior part of the osteotomy line was inclined proximally. The results of these studies^{7,23} suggest that the posterior tibial slope may increase or decrease depending on whether the osteotomy line is inclined anteriorly or posteriorly in the sagittal plane. However, the above-mentioned studies did not provide sufficient conclusions for quantitative analysis of the extent to which the change in the osteotomy inclination angle in the sagittal plane affects the change in the posterior tibial slope. Therefore, the present study aimed to verify how the anterior or posterior osteotomy inclination angle affects the tendency of change in the posterior tibial slope and to conduct a quantitative analysis to determine the extent of change in the posterior tibial slope according to the degree of change in the osteotomy inclination angle. The present study was based on the hypothesis that, with an increase in the inclination angle between the sagittal osteotomy line and the medial tibial plateau line, the degree of change in the posterior tibial slope after MOWHTO would also increase.

II. MATERIALS AND METHODS

1. Patients

Patients who underwent MOWHTO from November 2014 to November 2017 at our hospital were retrospectively reviewed after approval from the institutional review board of our institution. This study received exemption from informed consent by the institutional

review board. Research process was performed in accordance with the Declaration of Helsinki. The inclusion criteria were as follows: (1) symptomatic osteoarthritis in medial compartment treated with MOWHTO, (2) varus alignment of the lower extremity (hip-knee-ankle angle $> 5^\circ$), (3) no fracture or osseous deformity of the index lower extremity other than osteotomy surgery, (4) no previous surgery around the index knee, and (5) no ligament injury of the index knee.

2. Surgical procedure

The preoperative planning of MOWHTO was designed on the standing anteroposterior(AP) radiographs of the whole lower extremity. The correction angle was measured with the Miniaci method.²⁸ The weight bearing line was aimed to pass through the Fujisawa point (62.5% of the entire tibial plateau from the medial edge) after realignment. Prior to the conduction of MOWHTO, arthroscopic examination was performed. After the arthroscopy, skin incision was made obliquely on the medial aspect of the proximal tibia, and subperiosteal release of the superficial medial collateral ligament was performed. Under the image intensifier, the first Kirschner wire was inserted from the anteromedial cortex of tibia approximately 3.5cm distal to the joint line towards near the tip of the fibular head, known as the “Safe zone”.¹² In order to create the parallel osteotomy relative to the medial joint line in the sagittal plane, the knee joint was slightly flexed and the angle of the fluoroscopy was adjusted to obtain the true lateral view of the knee joint, overlapping the medial and lateral femoral condyles.¹⁹

Under the maintenance of the true lateral view on the fluoroscopy, a guide pin was temporarily put over the skin just above the entry point of the first Kirschner wire to be parallel to the medial joint line. Then, an additional second Kirschner wire was inserted

just below the guide pin and advanced along the direction of the first Kirschner wire as parallel as possible. These 2 Kirschner wires determined the osteotomy line in the sagittal plane. The first transverse osteotomy was conducted just below the 2 Kirschner wires, ensuring the osteotomy line extending up to 1cm medial to the lateral cortex of the tibia. The second ascending osteotomy was followed. With four-chisels, the transverse osteotomy was opened gradually with caution. To achieve the planned osteotomy gap, the TomoFix bone spreader was used for osteotomy site opening and measurement. For the prevention of change of the posterior tibial slope, the anterior to posterior opening gap ratio was kept at approximately two to third.³⁷ The proximal tibia was fixed with a Tomofix plate (DePuy Synthes, West Chester, PA, USA) and locking screws to maintain the osteotomy gap.

3. 3D reconstruction of computed tomography images

A postoperative lower leg CT scan from the distal femur to the ankle joint, including the entire tibia, was conducted for all patients on the day of the surgery, with the knee in a fully extended position, to determine the postoperative status related to osteotomy surgery, such as lateral cortical hinge fracture and plate and screw position. The CT scans (Sensation 64, Siemens Healthcare, Erlangen, Germany) had following parameters: tube voltage of 120 kVp, tube current of 135–253 mA, acquisition matrix of 512 pixels × 512 pixels, scan field of view of 134 to 271 mm, and slice thickness of 0.6 to 1 mm. Digital Imaging and Communications in Medicine (DICOM) data of the postoperative computed tomography (CT) images of the included patients were extracted from the picture archiving and communication system (Centricity PACS, GE Medical System Information Technologies, Milwaukee, Wisconsin, USA). The extracted DICOM files were imported into Mimics software (version 17; Materialise, Leuven, Belgium). Using this software, 3D

reconstruction work was conducted for distal femur and tibia from the proximal part to mid shaft. Segmentation process between the bone, metal, and surrounding tissues was performed through manual thresholding works. After 3D reconstruction of femur, tibia, plate and screw was completed, distal femur was digitally removed first to leave only the 3D model of the proximal tibia that was fixated with plate and screws (Figure 1-A). And then, the plate and screws were also digitally eliminated so that the 3D model contained only the tibia bone (Figure 1-B). Thereafter, the 3D tibia model was restored to its pre-osteotomy original tibia by rotating the proximal tibia segment. The location of the hinge for the rotation was the innermost part of the osteotomy, which was used when opening the osteotomy during MOWHTO. The line where the lowermost osteotomy plane of the proximal tibial segment and the uppermost osteotomy plane of the distal tibial segment intersected was set as the axis of rotation. It was located approximately 1.0 cm medial to the lateral cortex and 1.5 cm below the joint surface in the coronal plane(Figure 1-C).^{6,29} The rotate tool in Mimics software was used to restore the original tibial model. The tibia model was arranged so that the axis of rotation could be seen as a single point, and the center of rotation in the rotate tool was positioned at that point. The pre-osteotomy original 3D tibial model was restored by rotating the proximal tibial segment until both the upper and lower osteotomy planes met, and the proximal and distal part of the medial cortex of the tibia came into contact with each other (Figure 1-D). The amount of rotation was almost the same as the correction angle performed during each patient's operation.

Figure 1. Steps to create a three-dimensional (3D) model of a pre-osteotomy original tibia. (A) Reconstructed 3D model of tibia without soft tissue. (B) Virtual elimination of plate and screws from the 3D model. (C) Rotation axis setting with the position about 1.0 cm before the lateral cortex and 1.5 cm below the articular surface as the hinge for restoration to pre-osteotomy original tibia. (D) Restoration to preoperative status of tibia by rotating the proximal segment around the rotation axis and eliminating the osteotomy gap.

4. Simulation of MOWHTO for the 3D reconstructed tibial model

To verify the effect of anterior or posterior osteotomy inclination angle on the tendency of change in the posterior tibial slope and to quantitatively analyze how much the posterior tibial slope changes according to the degree of change in the osteotomy inclination angle, osteotomy with various inclination angles in the sagittal plane was performed on the restored 3D tibia model. To perform the virtual osteotomy, the tibial coordinate system was first determined by defining the x -, y -, and z -axes in the 3D model. The x - and y - axes were located on the joint plane of the tibia. To clarify the conditions for creating the joint plane of the tibia, 3 points were set on the surface of the tibial plateau according to the previous study.¹⁶ The first point is on the most medial point of the medial tibial plateau, the second one is on the most posterior point of the medial tibial plateau, and the third one is on the most lateral point on the lateral tibial plateau. These 3 points made a joint plane of tibia (Figure 2-A). The x -axis was defined as the line formed by each midpoint on the surface of the medial and lateral condyles of the tibia. To define the x -axis on the joint plane of the tibia, the midpoint of each plateau was established by the best-fit circle method.⁴⁰ Two circles that best fit the peripheral margin of medial and lateral plateaus were drawn on the joint plane. The centers of the best-fit circles were marked as the midpoint, and the line connecting the two midpoints was defined x -axis. The y -axis was determined as the vector perpendicular to the x -axis in the axial plane, and the z -axis was determined as the vector perpendicular to the x -axis in the coronal plane. (Figure 2-B).

Figure 2. Determination of the joint plane and the coordinate system of proximal tibia by defining the x -, y -, and z -axes in the 3D model. (A) The joint plane was defined by the 3 points (the most medial point of the medial tibial plateau, the most posterior point of the medial tibial plateau, and the most lateral point on the lateral tibial plateau). (B) The x -axis was defined by the line connecting the centers of the best-fit circles of the medial and lateral plateau on the joint plane. The y - and z -axes were defined by cross-product of the x -axis.

After defining the x -, y -, and z -axes, the true lateral position of the 3D tibial model was obtained by manipulating the femur so that the medial and lateral condyles were overlapped in the sagittal plane.¹⁹ At the same time, the y -axis was positioned horizontally and parallel to the ground, in accordance with a previous study.¹⁹ To leave only the tibial model, the femur was virtually eliminated. Following this, the coronal plane of the 3D model was obtained by rotating the model by 90° around the z -axis. Second, three points were determined to set the osteotomy plane. In the coronal plane, point 1 (P1), the starting point of osteotomy, was placed on the anteromedial cortex of the proximal tibia, 3.5 cm below

the medial end of the tibial plateau.⁶ Point 2 (P2), which was used as a hinge, was located 1.0 cm medially from the lateral cortex of the tibia on the *x*-axis, 1.5 cm below the articular surface on the *z*-axis (Figure 3-A)^{6,13,29}, and at the midpoint of the entire length of the anteroposterior articular surface on the *y*-axis (Figure 3-B). In addition to P1, as one of the two guide points for initiating the osteotomy, point 3 (P3) was placed on the posteromedial tibial cortex in the sagittal plane. The line connecting P1 and P3 was determined the sagittal osteotomy line (Figure 3-C).

Figure 3. Positioning of point 1 (P1), point 2 (P2), and point 3 (P3) on the three-dimensional (3D) images of tibia. (A) Initially, P1, the starting point of osteotomy, was placed on the anteromedial cortex of proximal tibia, 3.5 cm below the medial end of the tibial plateau. P2, which was used as a hinge, was located 1.0 cm medially from the lateral cortex of tibia on the *x*-axis and 1.5 cm below the articular surface on the *z*-axis. (B) In the axial plane, P2 was positioned at the midpoint of the entire length of anteroposterior articular surface. (C) In the sagittal plane, P3 was placed at the posteromedial cortex of tibia. The angle

between the line formed by P1 and P3 and the line of the medial tibial plateau was defined as the osteotomy inclination angle in the sagittal plane.

The angle between the line formed by P1 and P3 and the line of the medial tibial plateau was defined as the osteotomy inclination angle in the sagittal plane. In order to obtain an osteotomy line parallel to the medial tibial plateau line in the sagittal plane, P3 was positioned such that the line formed by P1 and P3 was parallel to the medial tibial plateau line. By changing the position of P3, while P1 and P2 were fixed, the osteotomy inclination angle could be changed (Figure 4).

Figure 4. In the sagittal plane, the angle between the dotted line formed by P1 and P3 and the solid line parallel to the medial tibial plateau line was defined as the osteotomy inclination angle. (A) Parallel osteotomy line (0°). (B) Anteriorly inclined osteotomy line (10°). (C) Posteriorly inclined osteotomy line (-10°)

Third, osteotomy was performed virtually along the osteotomy plane formed with 3 set points. The osteotomy gap was opened according to the correction angle applied to each patient at the time of the actual surgery, as measured using the Miniaci method.²⁸ The osteotomy gap ratio between the anterior and posterior openings was set to 0.67, based on a previous study.³⁷ (Figure 5)

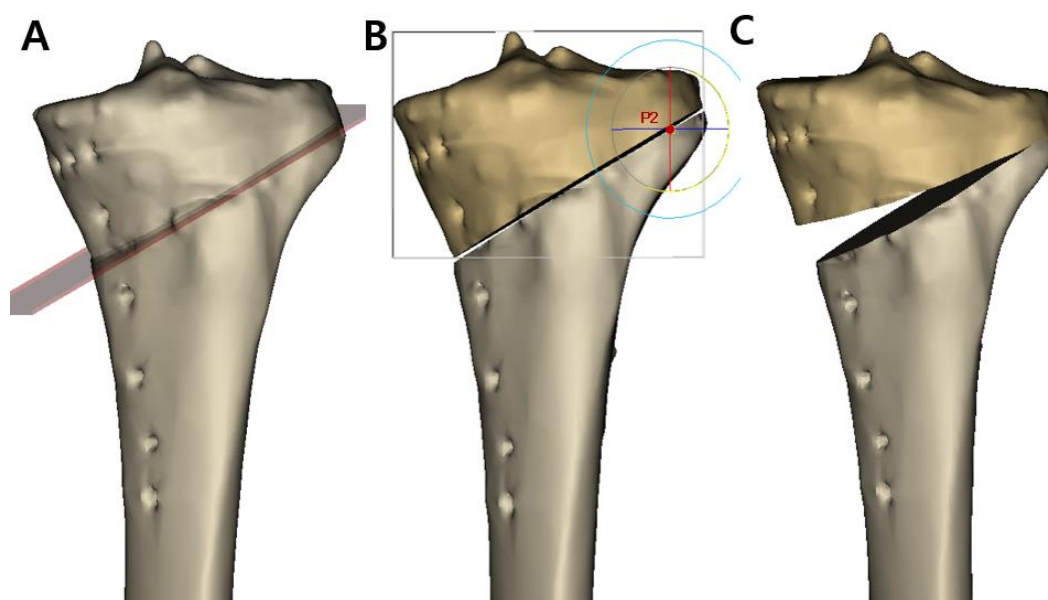

Figure 5. Simulation process of virtual osteotomy. (A) The osteotomy plane was formed with 3 set points. (B) The osteotomy was conducted along the osteotomy plane, and position of hinge was located (P2). (C) Using the P2 as a hinge, the proximal segment was opened according to the correction angle applied to each patient at the time of actual surgery, as measured using the Miniaci method.

Various osteotomy inclination angles in the sagittal plane were applied to the 3D tibial model. The osteotomy inclination angle was changed from -30° to 30° at intervals of 5° by changing the position of P3 (Figure 6). The angle value was classified as positive in case of an anteriorly inclined osteotomy, in which the anterior part of the osteotomy line was inclined distally compared with the line parallel to the medial tibial plateau line (Figure 6-A). Conversely, the angle value was classified as negative in the case of posteriorly inclined osteotomy, in which the anterior part of the osteotomy line was inclined proximally (Figure 6-B). To make an anteriorly or posteriorly inclined osteotomy, P3 was set proximal or distal to the line passing through P1 while passing parallel to the medial plateau line. A total of 13 osteotomies were performed for each 3D tibial model at intervals of 5° for inclination angle from -30° to 30° .

Figure 6. Simulation of osteotomy was performed. Thirteen osteotomy inclination angles in the sagittal plane were applied to the three-dimensional tibial model. The osteotomy inclination angle was changed from -30° to 30° at intervals of 5° by changing the position of P3. The anterior-to-posterior osteotomy opening gap ratio was maintained at 67%. (A) Anteriorly inclined osteotomy (0° , 10° , 20° , 30°). (B) Posteriorly inclined osteotomy (0° , -10° , -20° , -30°).

5. Measurement of the posterior tibial slope with 3D tibial model

The posterior tibial slope was measured on the 3D tibial model. In a true lateral position¹⁹, the image of the 3D tibial model was captured and measurement of the posterior tibial slope was conducted as presented in a previous study.⁷ The posterior tibial slope was defined as the angle formed by the medial tibial plateau line and the line perpendicular to the line bisecting the tibial shaft (Figure 7). For each case, the posterior tibial slopes were measured using an original tibial model that was restored to the preoperative status (Figure 7-A) as well as 13 simulation experimental models by virtual osteotomy (Figure 7-B).

Figure 7. Measurement of the posterior tibial slope. In a true lateral position, the image of the 3D tibial model was captured and the posterior tibial slope was measured. The medial tibial plateau line and the line perpendicular to the line bisecting the tibial shaft were drawn. Posterior tibial slope was defined by the angle formed by these two lines. (A) Posterior tibial slope of the preoperative original tibia. (B) Posterior tibial slope of the virtually osteotomized tibia. PTS = posterior tibial slope

6. Statistical analysis

Repeated measured analysis of variance (ANOVA) was used to compare the postoperative posterior tibial slopes after the virtual osteotomy with each other. The sphericity of the data was confirmed by Mauchly's test. As the sphericity was not met, Huynh-Feldt correction was used. To make pairwise comparisons, the post hoc analysis with adjusted P-value was conducted by Bonferroni correction. A paired *t*-test was used to compare between the postoperative posterior tibial slope after virtual osteotomy with each sagittal osteotomy inclination angle and the posterior tibial slope measured in the original preoperative tibial model. A linear mixed model was used to analyze the effect of the sagittal osteotomy inclination angle on the change in the posterior tibial slope. In the linear mixed model, the Akaike information criterion (AIC) and Bayesian information criterion (BIC) were compared, and the model with a smaller AIC or BIC value was selected as the final model.²¹ The coefficient (β) was obtained from a linear mixed model under a random intercept model with a first order autoregressive structure. The level of significance was set at $P < 0.05$. Statistical analyses were conducted using the IBM SPSS Statistics for Windows software (version 26.0; IBM, Armonk, New York, USA). The scatter plot was obtained using the R statistical software (version 3.6.2; R Foundation for Statistical Computing, Vienna, Austria).

III. RESULTS

Thirty knees from 30 consecutive cases meeting the inclusion criteria were included. The demographic data of all the patients included in this study are listed in Table 1. Nine of the 30 patients were male (30%) and 21 were female (70%), with an average age of 56.2 years (range, 43–61 years) and average body mass index of 26.9 kg/m² (range, 23.2–30.0 kg/m²). The mean preoperative and postoperative hip-knee-ankle angles were -6.5° (range, -4–10.9°) and 2.6° (range, 0.7–4.7°), respectively. The mean preoperative weight-bearing line ratio was 21.1% (range, 10.3–35.7%), and the mean postoperative weight-bearing line ratio was 61.1% (range, 53.1–73.0%). The mean correction angle was 10.3° (range, 6.4–16°), and the mean preoperative posterior tibial slope, measured using the restored original 3D tibial model, was 8.9° (Table 1).

Table 1. Demographic data of patients

Parameter	Overall cohort (n =30)
Age (years) ^a	56.2 ± 2.7
Sex (Male / Female) ^b	9 (30%) / 21 (70%)
Affected side (Right / Left) ^b	14 (46.7%) / 16 (53.3%)
Height (cm) ^a	159.2 ± 7.4
Weight (kg) ^a	68.0 ± 9.0
Body mass index (kg/m ²) ^a	26.9 ± 3.0

1. Postoperative posterior tibial slope and posterior slope changes after virtual osteotomy

A total of 13 virtual MOWHTO simulations were performed for each 3D model in this study. When the anterior part of the osteotomy line was inclined distally compared to the line parallel to the medial tibial plateau line, the posterior tibial slope increased. As the osteotomy inclination angle increased, the mean change value in the posterior tibial slope also increased. Conversely, when the anterior part of the osteotomy line was inclined

proximally compared to the line parallel to the medial tibial plateau line, the posterior tibial slope decreased. As the absolute value of the negative number of posterior inclined osteotomy angle increased, the absolute value of the mean change in the posterior tibial slope also increased further (Table 2).

Table 2. Postoperative posterior tibial slopes measured on the 3D models where the virtual osteotomy was performed with various sagittal osteotomy inclination angle

Sagittal osteotomy inclination angle	Posterior tibial slope	Posterior tibial slope change
30°	11.3 ± 3.6	2.4 ± 0.8
25°	10.9 ± 3.6	2.0 ± 0.8

3. Analysis of the effect of sagittal osteotomy inclination angle on the change of the posterior tibial slope

According to the linear mixed model analysis, the sagittal osteotomy inclination angle had a significant influence on the change of the posterior tibial slope in both anteriorly and posteriorly inclined osteotomies ($P < 0.001$). When the sagittal osteotomy inclination angle was positive, an increase in the osteotomy inclination angle by 1° increased the posterior tibial slope by 0.079° ($\beta = 0.079$, $P < 0.001$). Conversely, when the sagittal osteotomy inclination angle was negative, a 1° decrease in the osteotomy inclination angle decreased the posterior tibial slope by 0.067° ($\beta = 0.067$, $P < 0.001$) (Table 6).

Table 6. Analysis of the effect of sagittal osteotomy inclination angle on the change in the posterior tibial slope by linear mixed model

	Anteriorly inclination		Posteriorly inclination	
	β (S.E)	P value	β (S.E)	P value
Inclination angle	0.079 (0.006)	<0.001	0.067 (0.004)	<0.001

The coefficients were obtained from a linear mixed model under a random intercept model with first order autoregressive structure. S.E. = standard error

Figure 8 shows the scatter plots of the posterior tibial slopes changes according to the 13 sagittal osteotomy inclination angles. The estimated means with 95% confidence interval obtained from a linear mixed model under the random intercept model also showed that osteotomy inclination angles of greater than $+10^\circ$ and less than -10° had statistical significant effects on the change in the posterior tibial slope.

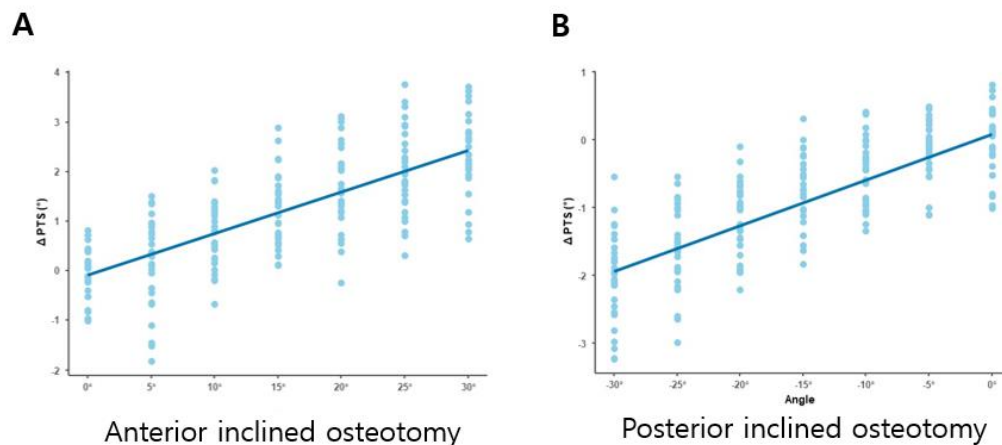

Figure 8. Scatter plots of the changes of the posterior tibial slopes according to the change of the sagittal osteotomy inclination angle. (A) Anteriorly inclined osteotomy. (B) Posteriorly inclined osteotomy.

IV. DISCUSSION

In MOWHTO, coronal realignment of the lower extremity is the primary focus,^{8,24} but change in the posterior tibial slope in the sagittal plane also can occur because proximal tibia is a 3D structure.³² The posterior tibial slope should be preserved after surgery to avoid unintended change in the biomechanics of the tibiofemoral joint caused by change in the posterior tibial slope.^{10,34} However, the posterior tibial slope has been reported to change after MOWHTO.³² Although osteotomy inclination angle in the sagittal plane is known as one of the variables affecting the change in posterior tibial slope,^{7,23} there is insufficient study on the effect of the sagittal osteotomy inclination angle on the posterior tibial slope. This study was conducted to verify how the anterior or posterior osteotomy inclination

angle affects the tendency of change in the posterior tibial slope and to conduct a quantitative analysis to determine the extent of change in the posterior tibial slope according to the degree of change in the osteotomy inclination angle. 3D simulation experiments were performed using 13 osteotomies for each tibial model. The findings of the current study present three principal implications. First, when there was an inclination angle occurred between the osteotomy line and the medial tibial plateau line in the sagittal plane, the posterior tibial slope changed after MOWHTO. Second, with respect to the line parallel to the medial tibial plateau line, when the anterior portion of the osteotomy line was inclined distally, the posterior tibial slope increased, and when the anterior portion of the osteotomy line was inclined proximally, the posterior tibial slope decreased. Third, as the absolute value of the osteotomy inclination angle in the sagittal plane increased, the degree of change in the posterior tibial slope also increased.

The changes in the posterior tibial slope were observed after MOWHTO when there was an osteotomy inclination angle with an absolute value of 10° or more between the osteotomy line and the medial tibial plateau line in the sagittal plane. Multiple factors need to be appraised during MOWHTO to prevent unwanted changes in the posterior tibial slope.^{7,23,33,37} The most common factor to influence the change in the posterior tibial slope is the opening gap ratio, which is derived based on the difference between anterior and posterior osteotomy opening gaps.^{33,37} However, the present study demonstrated that even if the osteotomy opening gap ratio is adjusted to an appropriate value of 2/3 during MOWHTO,^{37,38} the postoperative posterior tibial slope can change depending on the osteotomy inclination angle in the sagittal plane. These results are consistent with those of previous clinical studies.^{7,23} In addition, some previous studies have also argued that the posterior tibial slope did not change when an osteotomy line was created parallel to the

joint line.^{27,30} Miller *et al.*²⁷ suggested that making the sagittal osteotomy line parallel to the medial tibial plateau was essential to avoid the change of the posterior tibial slope. Moon *et al.*³⁰ recently reported an experimental simulation study using a 3D square column model, which showed that no significant difference in the posterior tibial slope change was observed when the osteotomy line was parallel to the posterior tibial slope. The results of the present study were consistent with those of the aforementioned studies. In actual MOWHTO surgery, most of the osteotomy lines have been reported to be non-parallel to the medial tibial plateau lines in the sagittal plane.^{7,23} Therefore, care should be taken to perform the osteotomy parallel to the medial tibia plateau line in the sagittal plane in order to avoid causing an unwanted change in the posterior tibial slope.

Furthermore, the findings of the present study revealed that the orientation of the sagittal osteotomy angle affected the increase or decrease in the posterior tibial slope. With respect to the line parallel to the medial tibial plateau, when the anterior portion of the osteotomy line was inclined distally, the posterior tibial slope increased, and when the anterior portion of the osteotomy line was inclined proximally, the posterior tibial slope decreased. Previous studies also have reported on the relationship between the osteotomy inclination angle in the sagittal plane and the change in the posterior tibial slope.^{7,23} Lee *et al.*²³ noted that 87.1% of the osteotomy lines were inclined anteriorly and the mean osteotomy inclination angle was 15.1° in the sagittal plane. Anteriorly inclined osteotomy in the sagittal plane was related to an increase in the posterior tibial slope. Chung *et al.*⁷ demonstrated the effect of the anteriorly and posteriorly inclined osteotomy on the posterior tibial slope. The mean increase in the posterior tibial slope was 1° in patients with an anteriorly inclined osteotomy line, whereas the mean decrease in the posterior tibial slope was 0.9° in patients with a posteriorly inclined osteotomy line. The results of the present simulation study were in

agreement with those of previous clinical studies. In the present study, 13 virtual osteotomies were performed for each 3D tibial model to systematically analyze the effect of osteotomy line orientation on the change in the posterior tibial slope. One osteotomy was performed parallel to the medial tibial plateau line, while six anteriorly inclined osteotomies and six posteriorly inclined osteotomies were performed at intervals of 5°. The results of this study showed that the posterior tibial slope increased in all cases of anteriorly inclined osteotomy and decreased in all cases of posteriorly inclined osteotomy. The virtual osteotomy simulation could exclude the other influencing factors that might affect the change in the posterior tibial slope, such as the osteotomy opening gap ratio, by adjusting the ratio to an appropriate value of 2/3. Therefore, the effect of the sagittal osteotomy inclination angle on the change in the posterior tibial slope could be more clearly elucidated in the present study compared to previous clinical studies.^{7,23}

Another notable finding in this study was that, as the absolute value of the sagittal osteotomy inclination angle increased, the degree of change in the posterior tibial slope also increased, regardless of whether the osteotomy line was inclined distally or proximally. According to the results of the linear mixed model analysis, the sagittal osteotomy inclination angle significantly affected the change in the posterior tibial slope in both anterior and posterior osteotomy inclinations, and the change value of the posterior tibial slope increased in proportion to the absolute value of the sagittal osteotomy inclination angle. When the sagittal osteotomy inclination was anterior, if the osteotomy inclination angle increased by 1°, the posterior tibial slope also increased by 0.079° ($\beta = 0.079$, $P < 0.001$). Conversely, when the sagittal osteotomy inclination was posterior, if the osteotomy inclination angle decreased by 1°, the posterior tibial slope also decreased by 0.067° ($\beta = 0.067$, $P < 0.001$). In addition, another noteworthy finding was that when the absolute value

of the sagittal osteotomy inclination angle was $\geq 10^\circ$, the posterior tibial slope changed significantly before and after osteotomy. According to a previous study¹, the mean sagittal osteotomy plane angle in 3D CT was 6.2° anteriorly, and this angle did not significantly affect the change in the posterior tibial slope. The results of this previous study differed from those of the present study in that there was no significant difference in the posterior tibial slope after osteotomy, although the sagittal osteotomy angle had an anterior inclination. However, the mean value of the sagittal osteotomy inclination angle in the previous study was 6.2° , which was less than 10° . Even in the present study, significant change appeared only at the angles of 10° or above, in agreement with Akamatsu *et al.*¹ To prevent an unintentional change in the posterior tibial slope, it is necessary to make the osteotomy line as parallel to the medial tibial plateau line as possible in the sagittal plane. Conversely, a change in the posterior tibial slope can be clinically used for effective treatment. If a change in the posterior tibial slope is required, the desired change can be achieved by determining the orientation and specific value of the sagittal osteotomy inclination angle during osteotomy, considering the numerical relationship between the sagittal osteotomy inclination angle and change in the posterior tibial slope. Increasing the posterior tibial slope would be beneficial in posterior cruciate ligament-deficient knee and genu recurvatum,^{5,10,31} whereas decreasing the posterior tibial slope would be helpful in anterior cruciate ligament-deficient knee.¹⁴

The present study had several limitations. First, this study was conducted by simulation using virtual osteotomy with a 3D reconstructed CT model. This might be different from the actual osteotomy due to possible anatomical variations of the proximal tibia and adjacent soft tissues, such as the pes anserinus or medial collateral ligament. However, simulation study can offer the advantage of performing several osteotomies on a single

tibia model. Second, the sagittal osteotomy inclination angles were set at intervals of 5° rather than continuous values. Thus, an accurate cut-off value of the sagittal osteotomy inclination angle that did not affect the change in the posterior tibial slope could not be obtained. Third, P2, which was used as a hinge, was located 1.0 cm medial to the lateral cortex of the tibia, and 1.5 cm below the articular surface in the coronal plane. However, there may be some individual differences of hinge location. Fourth, the observed change value in the posterior tibial slope was not large. Even when an osteotomy angle of 30° was given, the mean change in the posterior tibial slope was 2.4° , and a -30° osteotomy angle resulted in a mean change of -2.0° in the posterior tibial slope. The maximum change in the value of the posterior tibial slope was 3.72° . It has not yet been reported to what extent changes in the posterior tibia slope actually have a significant effect on the biomechanical aspect of the knee. However, previous studies have reported that even a small change in the posterior tibial slope affects the load on the anterior cruciate ligament.^{18,36} Further research is needed for an in-depth elucidation of the clinical significance of the change in the posterior tibial slope in relation to the sagittal osteotomy inclination angle.

V. CONCLUSION

The osteotomy inclination angle in the sagittal plane significantly affected the posterior tibial slope. When there was an inclination angle occurred between the osteotomy line and the medial tibial plateau line in the sagittal plane, the posterior tibial slope changed after MOWHTO. The posterior tibial slope tended to increase in anteriorly inclined osteotomy and decrease in posteriorly inclined osteotomy. The change in the posterior tibial slope was proportionally related to the absolute value of the osteotomy inclination angle. This study can help prevent unintentional changes in the posterior tibial slope during MOWHTO by

predicting the changes in posterior tibial slope according to the sagittal osteotomy inclination angle.

내측 개방형 경골 근위부 절골술시 수술 후 후방 경골 경사각의 변화를 막기 위해 시상면 상에서 절골 경사도가 내측 경골 고평부 선과 평행하게 시행되어야 한다. 하지만, 시상면 상에서 절골 경사도가 후방 경골 경사각에 미치는 영향에 대한 연구는 부족하다. 따라서 본 연구의 목적은 내측 개방형 경골 근위부 절골술시 전방 혹은 후방 절골 경사도가 후방 경골 경사각에 어떠한 영향을 미치는 지 확인하고, 절골 경사도 각의 변화에 따른 후방 경골 경사각의 변화에 대해 정량적 분석을 시행하기 위함이다.

실제로 내측 개방형 경골 근위부 절골술을 시행받은 30명의 환자들의 컴퓨터 단층 촬영 영상으로부터 의료 영상 프로그램을 이용하여 수술 전 3차원 경골 모델로 복원 하였다. 복원 과정은 프로그램 내에서 절골술 후 사용된 금속판 및 잠금 나사를 제거하고, 실제 수술 시 사용한 경첩에서 회전하여 개방된 절골면의 상, 하 절골면을 일치시켜 수술 전 경골의 3차원 모델로 복원하였다. 복원된 3차원 모델에 대해 가상으로 내측 개방형 경골 근위부 절골술을

실시하였다. 시상면 상의 절골 경사도는 절골 선과 내측 경골 고평부 선이 이루는 각으로 정의하였고, 전방으로 경사된 경우 양의 값으로, 후방으로 경사된 경우 음의 값으로 분류하였다. 각각의 3차원 모델에 대해 -30° 부터 $+30^\circ$ 까지 5° 간격으로 절골 경사도의 변화를 주어 총 13번의 가상의 절골술을 실시하였다. 가상의 절골술을 실시한 후 후방 경골 경사각을 측정하였으며, 절골 경사도와 후방 경골 경사각의 변화 간의 관계에 대해 분석하였다. 그 결과, 후방 경골 경사각은 가상의 절골술 전, 후로 시상면 상 절골 경사도가 5° , 0° , 그리고 -5° 인 경우를 제외하고 통계학적으로 유의미한 차이를 보였다 ($P < 0.001$). 선형 혼합 모델을 이용하여 전방 및 후방 경사도에 따른 후방 경골 경사각의 변화를 확인하였을 때, 전방 절골 경사도에서는 경사각이 1° 증가함에 따라 후방 경골 경사각은 0.079° 씩 증가하였고, 후방 절골 경사도에서는 경사각이 1° 감소함에 따라 후방 경골 경사각은 0.067° 씩 감소하였다. 내측 개방형 경골 근위부 절골술 시, 시상면 상에서 내측 경골 고평부 선과 평행한 선을 기준으로 절골선에 경사도가 발생할 경우 후방 경골 경사각은 변화는 것으로 밝혀졌다. 후방 경골 경사각은 전방 절골 경사도에서는 증가하는 결과를 보였고, 후방 절골 경사도에서는 감소하는 결과를 보였다. 후방 경골 경사각의 변화는 절골 경사도의 절대적 값의 변화에 따라 비례하는 것으로 밝혀졌다.

핵심되는 말 : 내측 개방형 경골 근위부 절골술, 시상면 절골 경사도, 후방 경골 경사각, 3차원적 시뮬레이션
