Introduction

Colorectal cancer is the third most common cancer worldwide, representing approximately 10% of all newly diagnosed cancers, and is the second leading cause of cancer-related mortality¹. Approximately 20% of colorectal cancers are located on the right side of the colon² and can be treated by right hemicolectomy using oncological principles.

The principles of 'oncological right hemicolectomy' have been an area of recent focus. A more thorough understanding of the importance of meticulous dissection to achieve complete mesocolic excision (CME) and central (D3) lymphadenectomy may improve outcomes in patients with node-positive disease³⁻⁵. In addition, minimally invasive techniques such as laparoscopy and robot-assisted surgery have become the standard of care⁶⁻⁸.

In many countries, surgery for colonic cancer patients is not centralized or restricted to high-volume units. This contrasts with rectal cancer, where centralization and specialization have long been believed to be key factors in outcomes and quality of care⁹⁻¹¹. Colonic cancer surgery is often performed by general surgeons in low-volume centres^{12,13}. This is notable, given the established correlation between centre volume and better outcomes in colorectal surgery^{13,14}. Consequently, continuous monitoring of surgical outcome quality is essential.

Various efforts have been made to evaluate and enhance the quality of colon cancer surgery. Previous classification systems primarily focused on measuring surgical results and outcomes through the evaluation of the surgical specimen. One of the earliest tools to validate the performance of adequate CME surgery was a pathological grading system introduced to assess

**Fig. 1** Distribution of minimally invasive right hemicolectomies across centres

Among 19 reference centres, a total of 3154 patients were analysed, of whom 686 (21.8%) were ideal patients and 2468 (78.2%) were non-ideal patients. The percentage of ideal patients for each centre is shown; this varied widely among centres, ranging from 1.7% to 51.2%.

the quality of colonic resections¹⁵. Similar to the assessment of total mesorectal excision (TME), this system rated the integrity of the surgical planes and the appropriateness of dissection levels. A subsequent classification, published by Benz *et al.*¹⁶, assessed the degree of radicality of resection by addressing missing mesocolic tissue and the surgical plane. However, both systems have important limitations, as neither of them accounts for patient factors, tumour stage, or surgical details.

Therefore, a comprehensive quality assurance tool for right hemicolectomy is needed.

Benchmarking is a quality improvement process that involves identification of best practice and facilitation of performance and outcome comparisons against the highest achievable standards, while considering a wide range of influencing factors and parameters¹⁷. Initially a well-established tool for quality assessment in business and manufacturing, benchmarking is now increasingly

adopted in surgical outcome research¹⁸. Several surgical procedures^{19–25} have been benchmarked according to a standardized approach that was validated through Delphi consensus^{18,26}.

Benchmark cut-offs for outcome parameters are determined using ideal patients, that is low-risk patients who have undergone surgery at high-volume centres. Therefore, they specify the best achievable outcome for a specific procedure. These benchmarks serve as reference values and thus enable surgical outcome comparison. Centres and surgeons can

compare their own performance to detect quality gaps to identify areas for improvement. Establishing benchmarks should lead to improved surgical quality and thus improved patient outcomes²⁶.

Although benchmark cut-offs have been established for several surgical procedures, they are to date not available for right hemicolectomy. The aim of this study was to establish benchmark cut-offs for frequently used outcome parameters for elective minimally invasive right hemicolectomy for adenocarcinoma of the ascending colon.

Table 3 Cohort validation

Methods

Study design

To establish international valid benchmark cut-offs for right hemicolectomies in right-sided colon cancer, the well-established ten-step approach was utilized¹⁸. Carefully selected centres that met specific criteria were included²⁶. Centres had to perform at least 250 colorectal resections annually or 100 per surgeon, maintain prospective data collection for oncological colorectal resections, conduct multidisciplinary tumour board discussions focused on colorectal tumours, and be actively involved in research in this field.

Colorectal specialist centres in Europe, North America, South America, Asia, and Australia were contacted based on these criteria by the investigators and invited to participate. The centres submitted pseudoanonymized data, free of patient identifiers, for all consecutive elective minimally invasive (laparoscopic or robotic) right hemicolectomies performed between July 2017 and June 2022 for adenocarcinoma of the caecum or ascending colon.

Study cohort

Inclusion criteria for patients were an age of ≥18 years, confirmed adenocarcinoma in the right hemicolon, and a follow-up interval of at least 6 months. Exclusion criteria were pathologies other than adenocarcinoma, tumour location in the transverse colon, synchronous colorectal cancer at another site requiring additional resections other than a right hemicolectomy, and open surgery.

Benchmarking

Patients were divided into two risk groups based on predefined parameters (Table 1). These were derived from established risk factors for postoperative medical and surgical complications following colorectal resection^{27–31}. Patients at low risk of complications were classified as 'ideal', whereas those at high risk of complications were classified as 'non-ideal'.

A total of 19 clinically relevant and widely used outcome measures were collected, including perioperative parameters, oncological parameters, procedure-specific complications, morbidity, and mortality (Table S1). Morbidity and mortality were assessed at hospital discharge, as well as at 3 and 6 months after surgery. Each complication was graded using the Clavien–Dindo classification (CDC)^{32,33}, while a patient's overall morbidity was summarized using the Comprehensive Complication Index[®] (CCI[®])^{34,35}. The selection of outcome parameters was based on their clinical relevance, consistent use in previous benchmark studies, and alignment with international guidelines, as well as the recent consensus recommendations on outcome reporting in surgery^{36–38}.

The benchmark cut-offs were derived from the ideal patient cohort of each individual centre. To prevent centres with a small number of ideal patients from disproportionately influencing the results of this study, a minimum of ten ideal patients per centre was required. Centres contributing fewer than ten ideal patients were included in the analysis only for the non-ideal cohort.

Statistical analysis

Data were collected in Excel (Microsoft, Remond, WA, USA). All analyses were performed using R Statistical Software version

4.3.2 (R Core Team, Vienna, Austria)³⁹. Discrete variables are presented as *n* (%) and continuous variables are presented as median (interquartile range (i.q.r.)).

Benchmark cut-off calculations were performed according to the previously published definition and in accordance with the Delphi agreement of experts^{18,26}. In short, benchmarks were set at the 75th percentile of all centres' median values for negative outcomes and at the 25th percentile of all centres' median values for positive outcomes.

Ethical approval

Ethical approval was obtained from the Canton Zurich, Switzerland (BASEC 2022-01200), as well as by each participating centre according to local regulations.

Results

Baseline data

A total of 21 centres from six continents submitted data on eligible patients.

Two centres were excluded from the analysis due to protocol violations or incomplete data sets with missing parameters needed to define ideal and non-ideal patients. Another two centres did not meet the minimum requirement of ten ideal patients, making only their non-ideal patients eligible for inclusion.

As a result, 17 centres from five continents (6 centres from Europe, 2 centres from North America, 2 centres from South America, 6 centres from Asia, and 1 centre from Australia) were included in the benchmark analysis for ideal patients, and 19 centres contributed to the non-ideal cohort.

Overall, 3154 patients were analysed, of whom 686 (21.8%) were ideal patients and 2468 (78.2%) were non-ideal patients. The proportion of ideal patients varied widely among centres, ranging from 1.7% to 51.2% (Fig. 1). Baseline characteristics for the overall cohort, as well as for ideal and non-ideal patients, are presented in Table 2. The ideal patient group was predominantly female (372 of 686 (54.2%)), had a median age of 64 (i.q.r. 56–71) years, and had a median BMI of 24.5 (i.q.r. 22.3–27.0) kg/m².

Validation of the ideal criteria

To validate the relevance of the selected parameters for distinguishing between ideal and non-ideal patients, postoperative outcomes were compared between the two cohorts (Table 3). Key parameters, such as length of hospital stay, R0 resection rate, number of resected lymph nodes, and complication rates, all showed statistically significant differences.

Benchmark cut-offs

Data from 686 ideal patients were used to establish benchmark cut-offs, which are listed in Table 4. Important benchmark cut-offs were an R0 resection rate of 100.0%, ≥96.9% of patients with ≥12 lymph nodes harvested, ≥23 lymph nodes harvested, and an anastomotic leak rate of ≤3.0%. At discharge, important benchmark cut-offs were a major complication (CDC grade ≥IIIa) rate of ≤5.6%, a median CCI[®] of 0, and a mortality of 0.0%.

Centre volume and outcomes

To assess the impact of centre volume on outcomes and quality, the participating reference centres were categorized into two groups: those performing ≥500 colorectal resections annually and those performing 250 to <500 colorectal resections

Table 4 Benchmark cut-off values for minimally invasive right hemicolectomy

Outcome parameter	Benchmark cut-off values*
Duration of surgery (min)	≤210
Conversion to open	≤5.7
ICU stay ≥3 days	≤1.7
Length of hospital stay (days)	≤6
R0 resection	100.0
Number of lymph nodes harvested	≥23
≥12 lymph nodes harvested	≥96.9
Anastomotic leak	≤3.0
Pancreatic fistula	0.0
Duodenal leak	0.0
Bleeding requiring transfusion	≤4.5
Bleeding requiring surgery	0.0

Mean CCI [®]	≤0
Mortality	0.0
At 3 months	
Any complication	≤37.9
Major complication (CDC grade ≥IIIa)	≤8.3
Median CCI [®]	0
Mean CCI [®]	≤2
Mortality	0.0
At 6 months	
Any complication	≤37.9
Major complication (CDC grade ≥IIIa)	≤8.3
Median CCI [®]	0
Mean CCI [®]	≤3
Mortality	0.0

Values are % unless otherwise indicated. *Benchmarks were set at the 75th percentile of all centres' median values for negative outcomes and at the 25th percentile of all centres' median values for positive outcomes. SSI, surgical-site infection; CDC, Clavien–Dindo classification; CCI[®], Comprehensive Complication Index[®].

annually. Data were analysed separately for the ideal and non-ideal subpopulations. Although all of the centres were high-volume specialized colorectal units, significant differences were observed regarding the number of lymph nodes harvested, complication rates and CCI[®], with centres performing ≥500 resections demonstrating superior results (Table 5).

Discussion

This international, multicentre study establishes benchmarks for oncological minimally invasive right hemicolectomy using a well-recognized benchmark methodology^{18,26}. It identifies the best achievable surgical outcomes for patients with adenocarcinoma of the right hemicolon treated at high-volume colorectal reference centres worldwide. These benchmark cut-offs encompass perioperative parameters, oncological quality indicators, procedure-specific complications, overall morbidity, and mortality. They serve as a reference for comparing data from individual surgeons, centres, and registries that should aid the improvement of healthcare quality.

The excellent results for ideal patients confirm the high quality achieved in specialized centres. Oncological quality indicators show an R0 resection rate of almost 100% for ideal patients. In addition, the median number of resected lymph nodes was 25 and therefore well above the required minimum. Further indicators of high quality are the low anastomotic leak rate of

Table 5 Impact of centre volume on surgical outcomes in ideal and non-ideal patients

only 2%, as well as the low conversion rate and the short length of hospital stay.

The high rate of reported complications is remarkable, with a complication rate of 20.1% in ideal patients and a comparatively low rate of severe complications (CDC grade ≥III) of 3.2%. These data suggest that the prospective databases of the participating centres were maintained to a high standard, as many CDC grade I and II complications were registered.

The most recent trial reporting outcomes after elective oncological minimally invasive right hemicolectomies is the observational MIRCAST study⁴⁰; the anastomotic leak rates ranged from 0.5% to 2.1% across the different surgical approaches and anastomotic techniques and were close to that for the benchmark cohort in the present study (median anastomotic leak rate of 2.0%; cut-off value of ≤3.0%).

Suspected procedure-specific complications such as pancreatic fistulas, duodenal leak, or major bleeding, all of which were widely discussed upon introduction of CME surgery, were rare in both ideal and non-ideal patients in the present analysis.

The differences in intraoperative bleeding between CME and D2 lymphadenectomy observed in the RELARC trial may be explained by the extent of lymphadenectomy performed around the superior mesenteric artery, an area not typically included in standard CME, which usually extends only to the superior mesenteric vein⁷. This example underscores the issue of inconsistent definitions and interpretation of D2/D3 lymphadenectomy in the literature and clinical practice. For this reason, in the present study, the authors deliberately refrained from including CME, D2 lymphadenectomy, or D3 lymphadenectomy as an outcome parameter.

The benchmark cut-off for conversion to open surgery was 5.7%. Although the reasons for conversion were not explored, the rate of laparoscopically performed right hemicolectomies might be a possible explanation (94.0% of procedures were performed laparoscopically in ideal patients). It is well known that conversion rates for robot-assisted procedures are lower. Spinoglio *et al.*⁴¹ published conversion rates of 0% for robot-assisted right hemicolectomies compared with 6.9% for laparoscopic procedures. In the present cohort, only 6.0% of

ideal patients and 7.2% of non-ideal patients were operated robotically. Therefore, most centres were still using the laparoscopic approach or might still have been in the learning curve phase for robotic surgery.

Although the impact of specialization and centralization is well established, and all included centres met the criteria for high-volume colorectal reference centres, there was a difference in outcomes among these top-tier hospitals, with better results associated with very high-volume centres. This probably reflects the additional effect of standardization and cumulative experience. There is no established threshold or ceiling effect, rendering the definition of high-volume colorectal reference centres inherently arbitrary by design⁴².

The limitation of the present study is the focus on minimally invasive procedures. Centres were asked to submit data on minimally invasive procedures only, assuming that the rate of procedures performed using an open technique does not change over time once a high-volume minimally invasive colonic surgery programme is established and only patient or tumour factors will lead to the performance of open surgery⁴³.

A further consideration is the applicability of these benchmarks in different healthcare settings. To ensure realistic and reproducible results, benchmark cut-offs are not based on single-centre outliers, but are conservatively set at the 75th percentile of all centres' median values for negative outcomes and at the 25th percentile of all centres' median values for positive outcomes. In many low-income countries, oncological right hemicolectomies are still predominantly performed using an open approach, which was not the focus of this analysis. However, once the necessary infrastructure for minimally invasive surgery is established, the same benchmark values should apply irrespective of geographical or economic context, providing a valuable tool for performance evaluation and quality improvement even in resource-limited environments.

This study establishes benchmark values for outcome parameters of minimally invasive right hemicolectomy that can be used as a performance reference for the evaluation of surgical care.
