Background: Intraoperative alfentanil is known to increase the epileptic discharge in the adult seizure patients. This study hypothesized that alfentanil might localize an epileptogenic focus in pediatric seizure patients.

Methods: This study was performed in the pediatric seizure patients who undergo second-staged operation. Thirteen pediatric patients were enrolled and their epileptic foci were already suspected from first operation. After anesthetic induction, sevoflurane was maintained at 0.6% end-tidal concentration for study period. Electrocorticography (ECoG) was recorded for 5 minutes before and 5 minutes after alfentanil 20 μg/kg IV. During the ECoG recordings, the mean arterial pressure (MAP) and heart rate (HR) were continuously monitored. After the surgery, a pediatric neurologist analyzed the changes of spike frequencies of suspected ictal zone. The spike frequencies of suspected non-ictal zone were also calculated in five patients. The suspected ictal zone was defined as the most abundant spontaneous spiking area observed after first staged grid insertion.

Results: Alfentanil induced a significant increase in spike activity of suspected ictal zone in 12 out of 13 patients (median of 20 [ranged 10 to 100] vs 38 [ranged 20 to 100], P < 0.05). Alfentanil-induced increase of spike activity was prominent in the suspected ictal zone rather than non-ictal zone. There were no significant changes in the MAP and HR after administration of alfentanil.

Conclusions: Alfentanil activates epileptiform activity of suspected ictal zone in pediatric patients with seizure disorder and can be used to assist in the localization of the epileptogenic focus during seizure surgery. (Korean J Anesthesiol 2007; 52: 47– 52)

Key Words: alfentanil, electrocorticography, pediatric, seizure.

INTRODUCTION

Patients with intractable seizures may be amendable to surgical treatment to eliminate or decrease the frequency of their seizures. Surgical treatment involves the resection of a seizure focus or interruption of seizure circuits. It is commonly performed as a two-staged procedure. Grid insertion surgery is performed to determine the location of the seizure focus during daily living life. Thereafter, excision of a suspected epileptogenic focus or interruption of seizure circuit is usually performed within two weeks. Intraoperative localization of a seizure focus is performed with electrocorticography (ECoG) using electrodes placed directly on the exposed brain. The purposes of intraoperative ECoG are to identify the location of the epileptogenic zone, to avoid the resection of nonepileptogenic brain tissue, and to determine the adequacy of the surgical resection.

Most anesthetics suppress the cortical activities, and it is not easy to identify the suspected ictal area under conventional surgical level of anesthesia. Therefore, it is often necessary to chemically stimulate the epileptogenic activity to aid in the localization of the epileptogenic focus. Many drugs have been used to activate epileptiform activity, including methohexital, propofol, sevoflurane and ketamine. Opioids are often used...
to localize the epileptogenic focus in adult patients. For example, alfentanil facilitates intraoperative ECoG-guided localization of the epileptogenic focus during seizure surgery. However, the effect of alfentanil on ECoG in pediatric patients with seizure disorder has not been studied. The etiology, pharmacologic responses and prognosis of pediatric seizure patients are different from those of adult patients.

The aim of this study was to investigate the effect of alfentanil on the intraoperative localization of an epileptogenic focus in pediatric patients with intractable seizure disorder.

**MATERIALS AND METHODS**

After approval from the institutional review board and informed consents from the patients, thirteen pediatric patients undergoing second-staged surgical resection of an epileptogenic focus were enrolled in this study. They underwent first-staged subdural grid insertion surgery within two weeks before second-staged operation. The patients were allowed to take their anticonvulsant medications until the time of surgery. No premedication was administered. All patients were monitored with electrocardiography, arterial blood pressure and pulse oximetry during the operation. The anesthetic technique was standardized. Anesthesia was induced with thiopental 5 mg/kg, and rocuronium 0.6 mg/kg was given intravenously for neuromuscular blockade. After tracheal intubation, the lungs were ventilated to maintain EtCO2 between 30-35 mmHg.

Anesthesia was maintained with sevoflurane, 50% oxygen in air and additional doses of rocuronium as necessary. The patient’s temperature was maintained within normal limits.

After induction, sevoflurane was maintained at 0.6% end-tidal concentration at least for 10 min before the study. During the study period, any surgical manipulations were not allowed. After 5 min of steady-state recording for a baseline ECoG, each patient received alfentanil 20 μg/kg IV, followed by 5 min of recording of ECoG after the administration of alfentanil. During the ECoG recordings, the mean arterial pressure (MAP) and heart rate (HR) were continuously monitored and documented for 5 min before and after alfentanil administration. Multi-channel analog ECoG recordings from the previously implanted subdural electrodes using an EEG-4421kTM (Nihon Kohden Corp., Tokyo, Japan) were recorded on paper by a pen-recorder. We were informed of the suspected ictal area from a pediatric neurologist. The pediatric neurologist was not allowed to participate in study period. The ECoG recordings before and after alfentanil administration were coded by unintended characters (Fig. 1). The most abundant spontaneous spiking area during awaken state at ward after first staged grid insertion was defined as the suspected ictal zone.

After the surgery, a pediatric neurologist analyzed the ECoG recordings and calculated the spike frequencies of suspected ictal zone before and after the administration of alfentanil. The spike frequencies of suspected non-ictal zone were also calculated in five patients.

Values are median number (range) or mean ± SD.
* P < 0.05 compared to the values measured before the administration of alfentanil.

Changes in MAP and HR were analyzed using the paired t-test. Comparisons of the changes of spike frequencies of suspected ictal zone before and after the administration of alfentanil were performed using Wilcoxon signed ranks test. P < 0.05 was considered significant.

RESULTS

Demographic data of 13 patients were shown in Table 1. Alfentanil induced a significant increase in spike activity in 12 out of 13 patients in suspected ictal zone (median value of 20 [ranged 10 to 100] vs 38 [ranged 20 to 100], P < 0.05) (Table 2) (Fig. 2). All patients showed spontaneous spikes before the administration of alfentanil in suspected ictal zone. The site of maximal activation induced by alfentanil was identical to the suspected ictal zone. Alfentanil-induced increase of spike activity was prominent in the suspected ictal zone.
rather than non-ictal zone (Fig. 2). No patient had electrographic or clinical seizure activity. There were no significant changes in MAP and HR after the administration of alfentanil (Table 2).

**DISCUSSION**

In this study, we investigated the effect of alfentanil on the intraoperative localization of an epileptogenic focus in pediatric patients with intractable seizure disorder. Intraoperative administration of alfentanil induced a significant increase in spike activity in suspected ictal zone.

Patients with seizures refractory to medical therapy may undergo surgical resection of a seizure focus or interruption of seizure circuits in an attempt to control their epilepsy. Accurate identification of the epileptogenic focus or surgical resection margin is important. Therefore, resection of an epileptogenic focus is often performed by ECoG monitoring. The obvious advantages of the intraoperative ECoG are to offer flexible placement of recording electrodes, to be performed before and after surgery to assess the presence or absence of epileptiform activity, and to allow direct electrical stimulation of the brain so that the regions involved in functions that must be spared by the resection can be delineated with a high degree of confidence. However, getting the precise information from ECoG is not easy during general anesthesia, as the anesthetics influence the recordings by suppressing electrical brain activity.

Opioids sometimes cause signs of neuroexcitation such as nystagmus, muscle rigidity, myoclonus, and seizure-like activity. Hence, opioids have been candidates for evoking epileptic activity to identify epileptogenic foci.

Alfentanil is a rapidly acting opioid analgescics with short duration of action and is often used to facilitate intraoperative ECoG-guided localization of the epileptogenic zone for adult patients. Cascino et al. retrospectively studied the effects of IV alfentanil 50µg/kg in 23 adult patients during surgery for intractable epilepsy under general anesthesia. They found an increased frequency of interictal epileptiform discharges in 20 patients, and the maximal effect of alfentanil occurred at 30 sec to 3 min after the administration of the drug. Our study showed that alfentanil 20µg/kg produced a similar degree of ECoG activation in pediatric patients.

Another more recent article reported the effect of alfentanil activation of epileptiform activity in children. Keene et al. noted that alfentanil 20µg/kg induced epileptiform activity in 83% of patients, and 25% of these patients had electrographic seizures. Many of these patients had mesial temporal foci, and epileptiform abnormalities appeared within 5 min in all cases. Our study showed that many of patients had frontal foci and no evidence of seizure activity was detected. Although we did not estimate the spike frequencies of suspected ictal and non-ictal zone in all patients, alfentanil-induced increase of spike activity was prominent in the suspected ictal zone rather than non-ictal zone.

Alfentanil is often used in anesthesia in a wide range of doses. Although the activation effect of alfentanil in epileptic patients is well documented, alfentanil does not seem to exert similar effect on the EEG of normal individuals. Bovill et al. did not observe electroencephalographic activation of epileptiform potentials following the intraoperative administration of alfentanil even with the dose of 120µg/kg IV into patients undergoing carotid endarterectomy.

Opioids can induce electrographic seizures during ECoG recordings in patients with epilepsy. Although the results of the previous studies confirm that remifentanil, alfentanil and fentanyl all activate epileptic discharges, these opioids in the doses employed had different effects on the epileptic threshold, and alfentanil seems to have more pronounced epileptogenic effects. Manninen et al. showed that two patients had electrographic evidence of seizure activity after the administration of alfentanil 50µg/kg. Contrary to them, we did not detect any evidence of ECoG or clinical seizure activity during the study periods with a dose of alfentanil 20 µg/kg in pediatric patients.

Sevoflurane is often used during neurosurgical procedures. For successful intraoperative ECoG monitoring, it is important for anesthesiologists to prevent the patient from intraoperative awareness as well as to minimize the effects of anesthetics on intraoperative monitorings. Kihara et al. showed that the minimum alveolar concentration (MAC)-awake of sevoflurane was observed to be 0.78 vol.% in children, and oral clonidine premedication of 2µg/kg reduced the MAC-awake to 0.36 vol.%. Watts et al. suggested that the capacity to modulate neuroexcitability is a dose-dependent feature of volatile anesthetic that is manifested most prominently at near burst-suppression doses (i.e., 1.5 times the MAC) and is minimal or absent at low doses. In our study, sevoflurane was maintained at 0.6% end-tidal concentration during the study periods of 10 min and alfentanil 20µg/kg IV was administered before the
recording. Therefore, intraoperative awareness and the effect of sevoflurane on the ECoG might be little concerned in our study.

The mechanisms underlying opioid-induced epileptogenic activity are poorly understood. Experimental evidence suggests that induction of epileptiform activity may be mediated through activation of multiple opioid receptor subtypes. A separate mechanism of activation may be mediated by opiate antagonism of inhibitory GABAergic neurotransmission. Zhang et al. showed that methohexital potentiates GABA-mediated synaptic inhibition and likely activates epileptiform activity at ECoG through a resulting increase in neuronal synchrony. The similar activation in interictal epileptiform activity seen at ECoG with opiates and barbiturates is interesting in that multiple mechanisms may underlie human epileptogenesis. Kofke et al. suggested that high doses of alfentanil administered to rats can produce limbic system seizure activity with hypermetabolism associated with neurophysiologic disturbances.

Surgical treatment for intractable seizure disorder is commonly performed on two-staged surgery for the precise detection of epileptogenic foci. If intraoperative alfentanil confers the capability of the localization of interictal area, it would be meaningful tool during one-staged operation in pediatric patients. However, it is unclear that alfentanil would increase the spike activities of epileptogenic foci regardless of the etiologies or anatomic locations. Furthermore, alfentanil may still act as proconvulsant.

In conclusion, we showed that alfentanil activates epileptiform activity in pediatric patients with intractable seizure disorder. Alfentanil can be used to assist in the localization of the epileptogenic focus during seizure surgery.
